Preface

The first reference text on surface mining was published by the American Institute of Mining, Metallurgical, and Petroleum Engineers, Inc., in 1968 and was appropriately titled "Surface Mining." That volume was the product of the dedicated labors of Professor Eugene P. Pfeider, his 3 coordinating editors, and 89 authors.

Now, 22 years later, the Society for Mining, Metallurgy, and Exploration, Inc. (formerly the Society of Mining Engineers of AIME) is publishing a completely new "Surface Mining" reference text. This book has involved a great deal of effort and perseverance by the authors, chapter editors, and coordinating editors. The intent of this revised edition was to completely rewrite, expand, and update the first edition to provide both a reference book for the working engineer and a textbook for the mining student. The book has taken far longer to prepare than the original ambitious plan and almost lost some of its authors, who had already written their contributions, when the Society had to shelve the project for two years due to financial constraints.

The Society and the profession are deeply indebted to the authors and editors who contributed both their knowledge and an enormous amount of time to this project. In addition, a very special acknowledgment is due to Marianne Snedeker, formerly Manager of Publications and currently Manager of Book Publishing, and her staff who have kept the project on course and organized during its development.

Special recognition is given the Seeley W. Mudd Memorial Fund Committee of AIME for financial support of the publication.

We hope that this publication will prove useful to many minerals industry professionals worldwide.

Table of Contents

Preface • <i>Bruce A. Kennedy</i>	iii
Contributors	iv
 Chapter 1. Introduction	
1.1 History of Mining • <i>M. Snedeker</i>	1
1.2 Current and Future Trends • <i>T.M. Li, M. Snedeker</i>	8
 Chapter 2. Exploration and Geology Techniques	
2.1 Overview of Exploration • <i>R.L. Brown</i>	15
2.2 Base Metal Exploration and Geology • <i>J.D. Lowell</i>	22
2.3 Precious Metals Exploration and Geology • <i>B.S. Hardie</i>	28
2.4 Uranium Exploration and Geology • <i>D.C. Fitch</i>	35
2.5 Iron Ore Exploration and Geology • <i>R.W. Marsden</i>	48
2.6 Coal • <i>W.E. Ward, II</i>	65
2.7 Placer • <i>W.H. Breeding</i>	77
2.8 Tar Sands Exploration and Geology • <i>J.A. Hennessy</i>	86
2.9 Oil Shale Exploration and Geology • <i>R.W. Elayer, I.P. Dorling, F.W. McKie</i>	91
2.10 Industrial Minerals • <i>R.H. Olson, E.H. Bentzen, III, G.C. Presley</i>	105
2.10.1 Asbestos	105
2.10.2 Barium and Strontium Minerals • <i>D.A. Brobst</i>	116
2.10.3 Borate Exploration <i>J.M. Barker</i>	120
2.10.4 Chromite	126
2.10.5 Clays	131
2.10.6 Diatomite • <i>F.L. Kadey, Jr.</i>	153
2.10.7 Feldspar	159
2.10.8 Fluorspar	163
2.10.9 Gypsum and Anhydrite	173
2.10.10 Kyanite and Related Minerals	181
2.10.11 Limestone and Dolomite • <i>D.D. Carr</i>	185
2.10.12 Lithium Raw Materials	194
2.10.13 Magnesite • <i>O.M. Wicken</i>	198
2.10.14 Manganese	201
2.10.15 Mica	204
2.10.16 Natural Abrasives	209
2.10.17 Nepheline Syenite	214
2.10.18 Olivine	218
2.10.19 Perlite • <i>F.L. Kadey, Jr.</i>	221
2.10.20 Phosphate Rock • <i>M.F. Dibble</i>	224
2.10.21 Pyrophyllite	230
2.10.22 Quartz/Silica Sand • <i>M.J. Zdunczyk</i>	235
2.10.23 Sand and Gravel • <i>H.B. Goldman</i>	237
2.10.24 Talc • <i>R.H. Olson</i>	242
2.10.25 Titanium	246
2.10.26 Vermiculite	260
2.10.27 Wollastonite • <i>G. Parkison</i>	262
2.10.28 Zeolites • <i>R.H. Olson</i>	266
2.10.29 Zirconium/Hafnium	268
2.11 Acquisition and Exercise of Rights to Use Land in Connection with Surface Mining Operations • <i>C.J. Parr</i>	273

Chapter 3. Ore Reserve Estimation

3.1	Introduction • <i>R.A. Bideaux</i>	287
3.2	Computerized Conventional Ore Reserve Methods • <i>H.P. Knudsen</i>	293
3.3	Statistical and Geostatistical Methods • <i>J.-M. Rendu, G. Mathieson</i>	301
3.4	Application of Methods	349
3.4.1	Precious Metal Deposits • <i>D.S. Bolin</i>	349
3.4.2	Reserve Estimation of Uranium Deposits • <i>H.M. Parker</i>	355
3.4.3	Coal Ore Reserve Estimation • <i>J.W. Boyd</i>	376
3.4.4	Iron Ore • <i>R.M. Hays, W.F. Betzler, P.A. Canton</i>	381
3.4.5	Placer Sampling and Reserve Estimation • <i>C.J. Wendt, S.W. Thomas</i>	385

Chapter 4. Feasibility Studies and Project Financing

4.1	Introduction • <i>G.E. Jackson, B.R. Waples, Jr.</i>	393
4.2	Feasibility Studies • <i>G.V. Borquez, J.V. Thompson</i>	396
4.3	Financial Aspects • <i>L.L. Brazda, H.A. Thornburg</i>	424
4.4	Project Financing • <i>E. Vickers, T. Ulatowski</i>	452

Chapter 5. Planning and Design of Surface Mines

5.1	Definition of Mining Parameters • <i>D. Armstrong</i>	459
5.2	Ultimate Pit Definition	465
5.3	Open Pit Optimization • <i>J. Whittle</i>	470
5.4	Optimum Production Scheduling • <i>E.L. Bohnet</i>	476
5.5	Materials Handling Ex-Mine • <i>R.G. Reed</i>	480
5.6	Waste Disposal — Planning and Environmental Protection Aspects • <i>E.L. Bohnet, L. Kunze</i>	485
5.7	Surface Coal Mines • <i>P.G. Morey</i>	495

Chapter 6. Mine Operations

6.1	Drilling	513
6.1.1	Drilling Principles • <i>H.L. Hartman</i>	513
6.1.2	Drilling Application • <i>A. Bauer, W.A. Crosby</i>	524
6.2	Blasting	540
6.2.1	Blasting • <i>A. Bauer, W.A. Crosby</i>	540
6.2.2	Design of Blasting Rounds • <i>R.L. Ash</i>	565
6.3	Overburden Removal • <i>G.E. Aiken, J.W. Gunnett</i>	584
6.4	Loading • <i>F.B. Sargent, T.I. Files, J.D. Humphrey</i>	620
6.5	Haulage and Transportation	658
6.5.1	Rail Haulage • <i>R.V. Ramani</i>	658
6.5.2	Trucks • <i>R.M. Hays</i>	672
6.5.3	Belt Conveyors • <i>L.D. Duncan, B.J. Levitt</i>	692
6.5.4	Ore Passes • <i>W.R. Goodner</i>	706
6.5.5	Scrapers • <i>R.M. Hays</i>	709
6.5.6	Wheel Loaders • <i>R.M. Hays</i>	715
6.5.7	Dozers • <i>R.M. Hays</i>	716
6.5.8	Haulage Systems Simulation Analysis • <i>R.V. Ramani</i>	724
6.5.9	Haulage System Analysis: Queuing Theory • <i>J. Elbrond</i>	743
6.6	Reclamation	749
6.6.1	Introduction • <i>L.W. Saperstein</i>	749
6.6.2	Reclamation Planning • <i>R.V. Ramani, R.J. Sweigard, M.L. Clar</i>	750

Introduction

Bruce A. Kennedy, Editor

1.1. History of Mining

MARIANNE SNEDEKER

INTRODUCTION

A fascinating thread that runs through the history of mining is the continuing evolution of mining methods. Often, the initial exploitation of a deposit involved rudimentary scratching at outcrops and picking up pieces of ore from the surface. This surface method was then followed in many instances by the development of underground workings in the form of shafts and galleries. Finally, a surface operation, often on a large-scale, would take place. Two prime examples of this sequence of evolution are the Rio Tinto mines in Spain and the copper operations at Butte, Montana.

Mining was the second of man's endeavors—agriculture was the first. Since prehistoric times, mining has been integral and essential to man's existence (Hartman, 1987). Surface mining was certainly not a 20th century invention. The earliest relatively large-scale mining for outcropping native copper occurred between 5000 and 15,000 BC. Rock fragmentation was usually achieved by the cyclical application of fire and water; loading and haulage was performed by manual labor with stone, wooden, and bronze tools for excavation and animals and human beings were used for haulage (Michaelson, 1979).

EARLY ENDEAVORS

Mining began with Paleolithic man about 450,000 years ago. The first known mining was for nonmetallics (industrial minerals) where man recovered raw stone materials from surface excavations and shaped them by crude fabrication techniques. Flint instruments have been found with the bones of early man (Hartman, 1987) and early excavations for flint have been found in Obourg and Spiennes, Belgium. Utensils made from clay that date from 30,000 to 20,000 BC have been found in Czechoslovakia (Beall, 1973) and graphite, sometimes called "Plumbago" or "Black Lead," was used by primitive man to make drawings on the walls of caves and by the Egyptians to decorate pottery (Graffin, 1982).

The first use of metals was for decoration rather than for utility purposes because of their unusual character and rarity (Raymond, 1986). Metallic minerals particularly attracted early man and he usually used them in their native form, retrieved, probably, by washing river gravel in surface placers (Hartman, 1987). According to Agricola (1950) early exploration methods included trenches and "a divining rod shaped like a fork."

The cultural stages of the evolution of man are associated with minerals and are the Stone Age (prior to 4000 BC), Bronze Age (4000 to 1500 BC), Iron Age (1500 BC to 1780

AD), Steel Age (1780-1945), and the Nuclear Age (since 1945), according to Hartman (1987). A chronology of developments in mining technology is given in Table 1.1 (Hartman, 1987).

Mining was common in ancient times around the perimeter of the Mediterranean Sea. Greek writers, Heroditus and Aristotle, both mention mining (Beall, 1973) and caves in Spain that were occupied as early as the Paleolithic period (before 10,000 BC) and gravel deposits nearby have yielded artifacts of gold with a sun-religion significance (Dunning, 1970). Mining in the Rio Tinto district of Spain began far before the dawn of recorded history. The largest open pit in the area, the Atalaya, has old underground workings now cut by more recent surface diggings. The early inhabitants, the Iberians, had both gold and silver ornaments (Joralemon, 1973).

Bronze Age

Evidence of early copper mining exists in many parts of the world. For example, a recent archeometallurgical expedition has uncovered a prehistoric mining complex at Phu Lon ("Bald Mountain") on the Mekong River in Thailand, that may be dated as early as 2000 BC. Workers at this complex used massive river cobble mauls to break the friable skarn matrix that held quartz veins rich in malachite (Pigott, 1988). The world's oldest known copper smelting furnace, dating to 3500 BC, has been found near the modern Timna copper mine in Israel (Raymond, 1986).

The link between native copper and malachite might well have been suggested to Neolithic man by the common association of these two forms of the metal in outcrops. But the process by which he then learned how to extract copper from the malachite remains an historic mystery. One suggested answer is that both metal smelting and pottery making appeared to have evolved about the same time. The potter, the first technician in the management of heat, had under his control all the materials and conditions necessary for smelting copper (Raymond, 1986).

The advent of both the Bronze and Iron Ages was contingent upon man's discovery of smelting and learning to reduce ores to native metal or alloy form.

The art of rock breakage by fire setting was the first technological breakthrough in mining (Hartman, 1987). Archaeological evidence of copper smelting indicate that the technique may not have spread from the Near East to other areas, as often thought, but began independently at a number of sites. Some of these sites are (Raymond, 1986):

Rudna Glava, Yugoslavia, before 4000 BC
 Italy, between 3000 and 2500 BC
 Britain by 1900 BC
 Scandinavia by 1500 BC
 India about 3000 BC
 Caucasus, southern Russia, by 2000 BC

The first true tin bronze appeared about 3000 BC with the earliest examples from the city states of Mesopotamia. In the following century, tin bronze was made in many areas of the Near East, including Egypt, Iran, Syria, Anatolia,

Cyprus. There was a society in Northern Thailand with bronze technology in the 3rd and 4th millennium BC. Bronze artifacts have been found in other locations in China (Raymond, 1986). Also in the Far East, Shang bronzes from Yin, China, settled about 1600 BC, are among the greatest artistic and technical achievements of early civilization.

Iron Age

The introduction of iron for making tools and weapons changed the life of early man in a vast number of ways. The earliest objects that have survived were made of meteoric iron, which contains a high percentage of nickel, and which were picked up from the ground (Raymond, 1986).

The Hittites, who settled in Anatolia, are credited with the invention of "good iron," and they flourished from 1400 to 1200 BC. After the Hittite kingdom was destroyed by European tribes, iron began to appear everywhere (Raymond, 1986).

The use of iron was made feasible through the development of three processes: "steeling," the addition of carbon to ore; "quenching," the sudden cooling of hot metal; and "tempering," the reheating of quenched metal to correct for brittleness. Steeling of iron seems to have developed in the Anatolia-Mesopotamia region of the Near East and then spread across Europe and Africa and into Asia (Raymond, 1986).

Greece and Rome

As the Iron Age progressed, new powers took over in the latter half of the 1st millennium BC as the older cultures of the Near East declined. The city-states of Greece were the first of these. One factor that made Greece—Athens, in particular—a great power was the rich silver-lead mines at Laurion. Once the silver mines in the hills of Attica became depleted, so too waned the Hellenistic world.

Rome replaced Greece as the dominant power and established a far-flung empire. Especially significant was the Roman conquest of immense mineral resources: gold in Gaul, Wales, the Balkans, and Persia; silver in the Pyrenees, Greece, and Anatolia; copper in Cyprus and the Sinai; and tin in Cornwall. A principal contributor to Roman mineral wealth was the Tartessus mine in Spain, now known as Rio Tinto, where the first exploitation was by trenches. The mine then went underground and today is a large open pit (Raymond, 1986).

Dark and Middle Ages

The Dark Ages descended after the Roman Empire fell and there was no advance toward a new level of civilization until almost the end of the 1st millennium AD. The interruption in the supply of metals was among many reasons for this standstill. The mining of metals ceased almost entirely in Europe, except for small quantities of easily accessible iron needed for weapons and tools (Raymond, 1986). A political development of significance to mining occurred in 1185 when the Bishop of Trent granted a charter to miners in his domain. It gave them legal as well as social rights, including the right to stake claims (Hartman, 1987).

Renaissance and Industrial Revolution

In Aachen, Germany, Charlemagne provided the leadership in the 9th century that began the emergence from the Dark Ages. He instituted drastic reforms in administration, finance, and education and he awakened a renewed interest in metals and metal working. Much of the wealth that made the Renaissance possible came from the Rammelsburg silver mine in the Harz Mountains. In addition, new deposits of silver and other metals were located in Saxony, Bohemia, and Moravia (Raymond, 1986).

Table 1. Chronological Development of Mining Technology*

Date	Event
450,000 BC	First mining (at surface), by Paleolithic man for stone implements
40,000	Surface mining progresses underground, in Swaziland, Africa
30,000	Fired clay pots used in Czechoslovakia
18,000	Possible use of gold and copper in native form
5000	Fire setting, used by Egyptians to break rock
4000	Early use of fabricated metals; start of Bronze Age
3400	First recorded mining, of turquoise by Egyptians in Sinai
3000	Probable first smelting, of copper with coal by Chinese; first use of iron implements by Egyptians
2000	Earliest known gold artifacts in New World, in Peru
1000	Steel used by Greeks
AD 100	Thriving Roman mining industry
122	Coal used by Romans in Great Britain
1185	Edict by bishop of Trent gives rights to miners
1524	First recorded mining in New World, by Spaniards in Cuba
1550	First use of lift pump, at Joachimstal, Czechoslovakia
1556	First mining technical work, <i>De Re Metallica</i> , published in Germany by Georgius Agricola
1585	Discovery of iron ore in North America, in North Carolina
1600s	Mining commences in eastern United States (iron, coal, lead, gold)
1627	Explosives first used in European mines, in Hungary (possible prior use in China)
1646	First blast furnace installed in North America, in Massachusetts
1716	First school of mines established, at Joachimstal, Czechoslovakia
1780	Beginning of Industrial Revolution; pumps first modern machines used in mines
1800s	Mining progresses in United States; gold rushes help open the West
1815	Sir Humphrey Davy invented miner's safety lamp in England
1855	Bessemer steel process first used, in England
1867	Dynamite invented by Nobel, applied to mining
1903	Era of mechanization and mass production open in U.S. mining with development of first low-grade copper porphyry, in Utah; while the first modern mine was an open pit, subsequent operations were underground as well

* Source: Hartman, H.L., 1987, *Introductory Mining Engineering*, John Wiley & Sons, New York, p. 6.

The foundation of mining law, on which the laws in many parts of the world today are based, was laid in this period in Saxony (Raymond, 1986).

One of the world's greatest developments occurred in the 15th century when Gutenberg developed the printing process using moveable type cast from a mixture of lead and tin. Following this invention, there was a tremendous exchange of technology in almost every field of human activity. One of these early technological works was Georgius Agricola's *De Re Metallica* (Raymond, 1986).

The industrial revolution meant a soaring demand for minerals and spectacular improvements in mining technology (Hartman, 1987). By the Middle Ages, the British had become the world's largest users of coal. The first recorded accounts of coal as a fuel came from China during the Han dynasty (206 BC to 220 AD). Coal was first used in Britain during the Roman occupation when pieces were picked up on the seashores. Once the Romans left in the 5th century, the use of coal dwindled until the end of the 1600s, when Britain, an island rich in both iron ore and carbon fuel, was suffering an energy crisis and industrial stagnation from the depletion of wood resources, used in iron working to make charcoal (Raymond).

Then in 1709 Abraham Darby prepared some coke from Shropshire coal, mixed it with local iron ore, and charged his blast furnace at Coalbrookdale. Slowly his method spread throughout England. An immediate result of this widespread change to smelting iron with coke was the increase in the demand for coal. This development freed England from industrial stagnation (Raymond, 1986).

There were a number of significant developments during the Industrial Revolution that profoundly affected mining technology. The first of these was James Watt's steam engine, perfected in the 1760s. It provided the stimulus for the production of coal and iron, the evolution of machine tools, and the development of new forms of transport for people and goods (Raymond, 1986). The air compressor was another great innovation and resulted in the late 19th century in the development of the air-driven rock drill (Beall, 1973). An impetus for mechanization was the invention of electricity which made applications of machinery more flexible (Beall, 1973).

The introduction in Hungary in 1627 of black powder as a blasting agent was an important change in mining practice. Soon afterward black powder was also being used in the Cornish tin mines (Beall, 1973).

The dawn of global civilization began with Columbus' discovery of the New World in 1492. His voyage meant that direct sea contact between far distant continents was about to be established (Raymond, 1986).

CENTRAL AND SOUTH AMERICA

Native Civilizations

The Indians in South America used native gold, silver, and even platinum in the 1st millennium BC, but copper objects do not appear until about 500 AD (Raymond, 1986). There is evidence in the pre-Inca period of the use of mineral resources—salt, clay, and chalk (Boggio, 1983).

The Inca period, which began in the 12th to 13th century AD, reached its peak at about the time of the discovery of America. The majority of gold production during this pre-Hispanic period was by exploitation of placers or gold-bearing gravels in rivers. There was an abundance of tin in the plateau area (Bolivia) and this supply almost certainly influenced the appearance of Bronze (Boggio, 1983). In Peru the age of metals, corresponding with the Tiahuanaco cul-

ture, began with the Christian era and lasted into the 14th century. There was lithic architecture of great dimensions; ceramics; and metalworking with gold, silver, and copper and tin, even attaining the level of bronze (Boggio, 1983).

Spanish Era

Beginning with the first voyage by Columbus, indications of gold were found in the newly discovered Caribbean islands (Prieto, 1973). During subsequent expeditions, Columbus established a mining camp at San Tomaso in San Domingo, from which he brought back more gold (Dunning, 1970). The Spanish explorers and conquistadores discovered and explored vast territories under the stimulus of a legend which told of a land abundant in gold (Prieto, 1973). Spain mined with the sword rather than the pick, as the conquistadores followed Columbus. In Peru they conquered the Incas, melted their mountains of gold decorative items, and cast the gold into ingots for shipment to Spain (Raymond, 1986).

Francisco Fernandez de Cordoba was exploring off the coast of the Americas in 1517 when he was blown off course in the Gulf of Mexico. He saw, on the Peninsula of Yucatan, evidence of a high civilization, the Mayans (Dunning, 1970). True mining by the Spaniards began in the lands discovered along the Gulf of Mexico in what was to be called New Spain. The first recorded copper mining by the Spaniards was in Cuba in 1524 (Beall, 1973). About 1525 the first silver mines exploited by the Spaniards were those of Morcillo in the present state of Jalisco, Mexico (Prieto, 1973). An event of great importance for the present-day Mexican iron and steel industry was the discovery in 1552 of the iron mines of Cerro de Mercado (Prieto, 1973).

Valdivia founded the cities of La Concepcion and Valdivia in Chile in 1550. At the same time rich gold mines were discovered in Confinas and Quilacoya (Prieto, 1973).

Peru proved to be a country rich in mineral resources. Henriquez Graces discovered mercury in 1558. The hill of Huantajaya, a rich silver deposit, was discovered in 1538 (Prieto, 1973). Cerro de Pasco had been a mining area for silver long before the arrival of the Spaniards. In colonial times great quantities of silver came from exploitation of surface deposits or *pacos* (Boggio, 1983).

In the district of Choco, Colombia, platinum was discovered in its natural state by Don Antonio de Ulloa and Don Jorge Juan in 1735 (Prieto, 1973).

In the Republican Period in Peru the first concession for exploiting guano deposits was signed in 1840. The 1830 nitrates began to be exploited at Tarapaca. The strong rise in copper price quotations in 1897 made this commodity one of the raw materials of great world demand and conditions were appropriate in Peru for a fast and growing participation in this market (Boggio, 1983).

Portuguese America

A search for riches was also responsible for the Portuguese exploration of the continent [South America] (Prieto, 1973). However, early attempts to find precious metals were not too successful. Some alluvial gold was discovered as early as 1541. The alluvial, gold-producing streams of Paranagua had been discovered by 1572, but production from the area was never large. The turning point came between 1693 and 1695 when Bandeirantes (Brazil's pioneers in the backlands) found rich gold placers in the Rio das Velhas, Rio das Mortes, and Rio Doce, north of Rio de Janeiro and west of Vitoria, in what is now the state of Minas Gerais. In 1721 new gold strikes were made at Cuiaba in Minas Gerais, followed five

years later by discoveries in the present state of Goiás (Prieto, 1973).

A Brazilian-born mineralogist, Manoel Ferreira de Camara Bethencourt e Sa (1765-1835) was the first to make pig iron at the Real Fabrica de Ferro do Morro do Pilar in Minas Gerais. The development of Brazil's iron industry dates from his time. Another development he fostered was the increased production of saltpeter, which induced him to set up a gunpowder factory (Prieto, 1973).

An event of profound importance was the discovery of diamonds in Minas Gerais by Bernardo da Fonseca in the mid-1720s. He found the diamonds in the gold washings of a place called Morrinhos in the Serro do Frio region (Prieto, 1973).

Recent History

Mention was made earlier of the importance of copper markets. The Incas first smelted copper from copper ores at Chuquicamata in the 1530s. Gold-quartz veins were found near the copper deposits but the Spanish were unable to do much with them because of the uninhabitable nature of the desolate and barren region of the Atacama desert. Modern exploitation did not begin until after 1881 when Chile established itself as the dominant power on the west coast of South America after the War of the Pacific. Initial investigation of Chuquicamata was made by churn drilling conducted by Edwin S. Berry and Walter A. Perkins in April 1912 (Parsons, 1933).

On Jan. 11, 1912, the Chile Exploration Co. had been organized by Guggenheim interests. The entire capital stock of the company was owned by the Chile Copper Co. of Delaware, organized 16 months later. Control of the company was acquired by the Anaconda Copper Mining Co. in 1923 (Parsons, 1933). William Braden formed Braden Copper Co. to develop the El Teniente mine in Chile. Control was subsequently bought by Guggenheim interests, later becoming Kennecott Copper Corp. Braden in 1913 founded Andes Copper at Potrerillos. The Chuquicamata mine followed in 1915.

The Cerro de Pasco Co. was formed by the Hearst-Haggin Syndicate with J. P. Morgan in 1902 and developed the mine at Oroya, Peru. After World War I, Cerro de Pasco developed the copper, lead, and silver mines at Morococha, Peru.

Since the early 1930s, nearly half the discoveries of great, low-grade copper ore bodies, usually dependent on large-scale surface mining, have been made in Peru and Chile (Joralemon, 1973).

In Peru Asarco won control of Toquepala and Quellaveco and Newmont acquired Cuajone. The two companies transferred their claims to Southern Peru Copper Co. Toquepala was opened in 1960 and Cuajone in 1964 (Joralemon, 1973).

In Mexico El Caridad was discovered between 1962 and 1968 and the Mexican government came to an agreement with Asarco to develop the property (Joralemon, 1973).

Changes in Peruvian mining laws in the period 1969-1978 led to the nationalization of many properties. In 1970 the state mining company, Empresa Minera del Perú, MINEROPERU, was formed. In the same year mining concessions that had been awarded to a number of companies were declared lapsed. Among those affected were Asarco, Cerro de Pasco, and Southern Peru Copper Corp. The concessions were then assigned to the new state company. On January 1, 1974, Cerro de Pasco was expropriated, it was stated, in the interests of the country and as a social necessity. The expropriated company became Empresa Minera del Centro del Perú, CENTROMIN-PERU (Boggio, 1983).

The Chilean government, in the same period, took similar action, forming Corporación Nacional del Cobre de Chile, CODELCO-Chile, the state company. The large mining operations at Chuquicamata, El Teniente, Andina, and El Salvador were expropriated.

NORTH AMERICA

Native Americans

Indians in Terra Incognita, the Spanish name for the vast southwest, part of which is now Arizona, mined salt, clay, pigment materials, stone, and turquoise by surface methods. There was quarrying of chert and obsidian for the manufacture of tools and weapons must have preceded most other forms of mining by several thousand years. The Apaches used vermilion cinnabar (mercury sulfide) as a body paint most probably taken from the mercury minerals found in La Paz county on the south flank of Cunningham Mountain in the Dome Rock mountain range. Here the Cinnabar mine was rediscovered by American prospectors in the 1880s (Canty and Greeley, 1987).

Probably as early as 3000 BC an elaborate copper culture began to grow up around the Great Lakes (Raymond, 1986). Copper articles were most common among the tribes that lived in what is now Michigan, Wisconsin, and the north shore of Lake Superior. Pits have been found that had existed long before the white man came. The original deposits were veins in the Keweenaw Peninsula on the south shore of Lake Superior (Joralemon, 1973).

Colonial Times

In the early days of settlement in North America, heavy bulk materials such as English brick, glass, and stone came from Europe as ship's ballast. In a very short time, extensive sand and clay deposits were utilized and the Boston, New Haven, New York, and Philadelphia area produced their own bricks. In the immediate areas around each of these commercial centers, lime and charcoal kilns were commonplace. Settlers moving back into the interior opened up deposits of marble, slate, soapstone, granite, limestone, and sandstone (Meade, 1988).

The first iron works was established at Saugus, MA, in 1646. It was imported from England and depended on the bog iron close by for feed. The Saugus works did not operate for many years, but the men who had worked there went elsewhere and helped set up forges and furnaces in the other Atlantic colonies (Raymond, 1986).

As the colonists gradually moved west into the interior, they exploited deposits as they found them. Two Frenchmen began mining lead at Mine la Motte in Missouri in 1718 (Beall, 1973).

Copper

There had been tales during the 17th and 18th centuries of extraordinary riches of copper along the shores of the Great Lakes in what is now Michigan. A geologist, Douglass Houghton, in 1840 went ashore by canoe on the Keweenaw Peninsula and found copper literally lying everywhere. After his report, there was a stampede of fortune hunters from the east who stumbled on the old Copper Culture of the Great Lakes. Who these early miners were is a mystery, since no burial grounds or other cultural evidence existed in the area—only mining tools and worked copper articles (Raymond, 1986).

The first modern-day mine in the area was the Cliff mine, discovered and opened by John Hays in 1843. This marked the first great mining boom in American mining history (Raymond, 1986).

Iron

Even as the first copper mines were being developed on the Keweenaw Peninsula, further west in the Michigan wilderness, a surveyor named Burt noticed erratic swings of his compass needle. With the help of a local Indian he had hired to help find outcrops of iron, in July 1845 he saw ahead of him a "mountain of solid iron ore 150 ft high. . . ." This first find turned out to be one of the world's largest deposits of iron, extending around the western shores of Lake Superior into Minnesota and Wisconsin. With the rich Mesabi Range at its core, the great iron province was to become one of the most productive ever known (Raymond, 1986).

The Mesabi Range was opened to development in the 1890s. Development of the steam shovel, which was to be vital in the development of the great copper porphyries, made surface mining the best possible exploitation method. Railroads went right into the pits. These procedures had clear economic advantages: they were cost efficient, resulted in larger production with fewer miners, and were simple to execute (Smith, 1987).

Gold Fever

Gold attracted the Spanish and Mexicans to the American Southwest, principally at first to New Mexico and Arizona and later California (Canty and Greeley, 1987).

Very little gold was found near the Atlantic coast, although a deposit in South Carolina, worked in the 1800s, is now being developed as a heap leach operation. Other deposits were located in Georgia and Virginia. In the west many deposits rich in gold and silver were found when the mountainous regions of Mexico were penetrated (Dunning, 1970).

California: In the 19th century gold was an inflammatory word in many parts of the world. In January 1848 James Marshall pulled a shiny pebble from the tailrace of Sutter's mill on the bank of the American River near Sacramento, CA. When news of the find became known, it started a stampede, as hordes of would-be miners poured into California to search for a fortune. In these workings, crude mining tools such as the wash bowl or pan, adapted from the paella pan of the Spanish settlers, were used. Early developments were the rocker, "long tom" cradle, sluices, and arrastras (crude, mule-powered crushers) used to separate gold-bearing sand from river gravel (Clamage, 1985; Raymond, 1986).

Colorado: In Colorado the search for gold had been going on for more than three centuries. In 1858 two prospecting parties were formed, one of which was made up of 19 Georgians. Most members of the two parties became discouraged and returned east; however, 12 Georgians headed by H. Green Russell stayed and established a camp near the mouth of Cherry Creek. Russell is credited with making the first important find about 80 miles above the mouth of the creek and other paying spots were found in the vicinity. Word reached the outside world and the Pike's Peak rush began (Dunning, 1970).

As a spinoff of this rush, prospectors climbed the mountains of Colorado and descended the canyons searching for gold and consequently a number of important mining districts were established in the period 1870-1900: the San Juans, Leadville, and Cripple Creek (Smith, 1988).

Nevada: When the rush to California subsided, many gold prospectors went in other directions. Among those returning via the Washoe were Peter O'Reilly and Patrick McLaughlin who did some placer mining around Washoe but were bothered by a heavy blue-black sand which clogged their sluice

boxes. They sent a sample to San Francisco for assay—the report showed that the heavy sand was almost pure silver. This was in about 1859. A third person, Henry P. T. Comstock, claimed to hold some interest in the land and although he only played a minor role in the discovery at Comstock/Virginia City, the lode was named after him (Dunning, 1970).

Butte, Montana: In 1863 placer gold was discovered in Bannock in western Montana. The next year a party of emigrants found gold at the foot of a long yellowish hogback at the north edge of the Summit Valley just west of the Continental Divide. The new camp was called Butte and a miniature gold boom lasted for several years. While visiting Butte in 1872, William A. Clark was attracted by the big copper-stained outcrops on the hill and bought several claims along the biggest copper showing. He turned the district into a flourishing silver producer, with copper production as a byproduct (Joralemon, 1973).

In 1875 the Walker Brothers, leading bankers in Salt Lake City, sent Marcus Daly to Butte to investigate the silver possibilities. He and Mike Hickey located the Anaconda and Nevadawater claims on a broad bank of yellow-stained, crushed rock that formed a bare streak across the slope of Butte Hill. This was the start of the Anaconda Co., developer of the "richest hill on earth" (Joralemon, 1973).

Alaska: A few early strikes, such as those at Juneau, had been made in Alaska. Prospectors found considerable gold along the 2000-mile Yukon River and its tributaries and by the fall of 1895 some spectacular finds had been made. A minor rush resulted at Forty Mile City in the Yukon. C. W. Carmack made a strike on Rabbit Creek in 1896 and it was this find that sparked the Klondike gold rush (Dunning, 1970).

The Porphyries

Two developments made possible the exploitation of the large, low-grade porphyry deposits in the US and South America. Progress in surface mining technology had been exceedingly slow with only minor changes in manually operated simple wheeled tools until finally steam shovels and rail haulage equipment were introduced in the early 1900s (Michaelson, 1979).

The second development was the flotation process. Largely pioneered in Australia, it soon spread worldwide and came to America just in time to compliment Daniel C. Jackson's innovation in open-cut mining at Bingham Canyon, Utah (Raymond, 1986).

Ely, Nevada, followed the Bingham Canyon operation. Jackson found the Ray, Arizona, and Santa Rita, New Mexico, properties. Miami and Inspiration came next. L. D. Ricketts and John Greenway developed the New Cornelia property at Ajo. Phelps Dodge developed Bisbee and Clifton-Morenci (Joralemon, 1973). Parsons (1933) lists the great power-shovel operations as Bingham Canyon, Chuquicamata, Nevada Consolidated (Copper Flat ore body), Chino, New Cornelia, and Sacramento Hill, Bisbee.

Recent History

In the US in the period 1930-1970 a number of large surface mining operations were developed. In the mid-1940s Phelps Dodge developed the Clay ore body, once considered too low grade to mine, and the Lavender pit in Bisbee in 1954. Around the turn of the century, Phelps Dodge had bought the Burro Mountain Copper Co., south of Silver City, NM, and in 1912 and 1915 bought two other properties in the area, now known as Tyrone. New developments in re-

covery techniques made it possible to treat the Tyrone oxidized ore and operations were started in 1969 (Joralemon, 1973).

Asarco began production at the Silver Bell ore body in Arizona in 1954 and started full production at the Mission mine in 1962 (Joralemon, 1973).

Pima in Arizona was brought on stream in 1959 by a joint venture of United Geophysical Co., Cyprus Mines Co., and Utah Construction and Mining Co. (Joralemon, 1973).

Duval opened two moderately successful properties at Copper Canyon and Battle Mountain in 1967. The Sierrita mine, one of the great ones, was opened in 1970 (Joralemon, 1973).

Anaconda bought the Twin Buttes and other properties from Banner Mining Co. and opened the property in 1971. Innovations were made in methods and equipment, such as high-speed belt conveyors for moving waste to the dumps (Joralemon, 1973).

Anaconda's mines at Butte had become deep and costs had increased to the point where many mines had been shut down. The company started a small open pit in the "Horse-tail" area under the low ground southwest of Butte Hill and the great Berkeley pit developed (Joralemon, 1973).

Canada

In more recent times, large surface operations have developed in Canada. Bethlehem Copper Corp., under the direction of H. H. (Spud) Huestis, opened its surface mine near Merritt, BC, in 1962, paving the way for a whole flock of profitable, low-grade, open-pit copper mines. Bethlehem also acquired the Valley Copper-Lake area northwest of the original property (Joralemon, 1973).

Placer Development Co., led by John Simpson, found the Craigmont property a few miles south of the Bethlehem and started production in 1961. Noranda developed Brenda Mines Ltd., 96.6 km (60 miles) southeast of Craigmont in 1970 (Joralemon, 1973).

Texas Gulf Sulphur Co. in the mid-1960s did exploration work in the area north of the Noranda underground operations in the Mattagami Lake area. The result was the Ecstall mine, which in 1967, the first full year of production, produced 44.6 kt (49,200 tons) of copper, 203.8 Mt (224,640 tons) of zinc, and 112.5 Mg (13,968,000 oz) of silver (Joralemon, 1973).

AUSTRALIA

Gold

Australia's early prime industry was agriculture, although coal was mined underground in the Hunter Valley. In 1851 Edward Hargraves, returning to Sydney from California, found a stretch of land in Bathurst that reminded him of the California diggings. He found gold and started a rush (Park, 1988). Gold was first mined in the Timbarra region of New South Wales in 1853, initially as alluvials in rivers draining the Timbarra Tablelands, followed by mining aplite dikes and weathered adamellite, the latter by sluicing (Anon, 1988a). After the discovery of gold in New South Wales, discovery of gold later that year in Victoria started an even bigger rush (Raymond, 1986).

In 1851 the government in Sydney charged 30 shillings a month for a miner's license (laborers received 5 shillings a day). The fee and other grievances stirred rebellious feelings among the diggers and the situation finally came to a head in 1854 on a Ballarat hillside named Eureka where 150 diggers behind a hastily built stockade were charged by troopers and overwhelmed; 25 were killed and 30 wounded. Some

reforms resulted (Parks, 1988). The discovery of gold in Victoria established the state in its own right, forced the issue of democracy through the Eureka Stockade, and established Melbourne as Australia's financial capital (Anon, 1988).

Other gold discoveries took place in southern Queensland, tropical Queensland, and the Northern Territory in the 1860s; at Mount Morgans, Queensland, 1883; and in the early 1890s at Kalgoorlie and Coolgardie, Western Australia (Chadwick, 1987).

During the gold rushes in eastern Australia, arid Western Australia felt left out since conventional panning methods could not be used because of the lack of water. A dry blowing method was developed in which wind was used to carry away the lighter silt and sand. The "shaker" resembled a hopper on wheels with a blower attached. One man shovelled in the gold-bearing sand while his partner shook the hopper and worked the blower. These operations proved highly successful and a new gold rush started in Western Australia (Dunning, 1970).

Other Minerals

"Cousin Jacks," Cornishmen who emigrated to America and Australia, contributed greatly to mining history. The Cornishmen who came to Australia "found a landscape which they could never have imagined existed, with outcrops of metals so rich they could not have believed it" (Raymond, 1986). In 1841 two Cornish miners, within an hour's walk of Adelaide, saw a shiny metallic-looking rock jutting out of a grassy hillside and recognized it as galena. The mine they opened—the first metal mine in Australia—was called Wheal Gawler and exploited veins of rich silver and lead (Raymond, 1986).

Dutton, a pastoralist, late in 1842 on a sheep run 60 km north of Adelaide, was riding through a rain storm when he saw a patch of vivid green on a hillside. It was malachite. At Kapunda it was bursting out of the hillside, so soft and rich, assaying 23% copper, that in a few minutes a man could fill a wheelbarrow with it (Raymond, 1986).

Enormous iron deposits were discovered at Pilbara in Western Australia and are now being mined at the rate of hundreds of millions of tons per year (Raymond, 1986).

AFRICA AND ASIA

South African Gold and Diamonds

In 1886 in South Africa, George Walker, a stone mason, picked up a peculiar rock and noticed what appeared to be flecks of gold in it. His friend George Harrison helped him determine that it was really rich in gold. This was the forerunner of the biggest and richest gold field (The Witwatersrand) ever found (Dunning, 1970).

Diamonds were discovered in South Africa in the 1860s. The Jagersfontein and Dutoitspan pipes were discovered in 1870, followed by the discoveries at Bultfontein, De Beers, and Kimberly in 1871. The Premier pipe, the largest in the country, was discovered in 1902 and it yielded the 3106-ct Cullinan gem diamond in 1905 (Chadwick, 1988).

Mining expanded rapidly in the Kimberley area in the 1870s, based on the Dutoitspan, Bultfontein, De Beers, and New Rush mines. Cecil Rhodes arrived at the diamond fields late in 1871. He brought some degree of mechanization to the "Big Hole," the name by which the Kimberley mines were known (Chadwick, 1988).

Central Africa

When Stanley made his first journey across Africa in 1873-1875, he found the natives wearing leg bands of beaten copper wire. Later explorers found natives mining rich ox-

idized copper in open pits. In the Belgian Congo there are old workings in more than a hundred separate copper ore bodies (Joralemon, 1973).

Robert Williams, a deputy of Cecil Rhodes, formed Tanganyika Concessions Ltd. in 1899 to develop the Katanga copper deposits. A Belgian company, Union Minière de Haut Katanga was formed in 1906, with Tanganyika Concessions as a large minority stockholder (Joralemon, 1973).

In Rhodesia Selection Trust, Ltd. and other companies developed the Roan Antelope, Mufulira, Nkana, and other mines of the northern Rhodesian Copper Belt (Joralemon, 1973).

Recent Developments

Palabora in South Africa was developed by Newmont Mining (manager), together with American Metal Climax (now Amax) and smaller South African companies. The mine began production in 1966 (Joralemon, 1973).

The O'okiep mine was opened in South Africa by Newmont in the 1930s (Joralemon, 1973).

In the Far East

Marcopper on Marinduque Island, New Guinea was developed by Placer Development and production started in 1969 (Joralemon, 1973).

Bougainville on one of the Solomon Islands started production in 1972 (Joralemon, 1973).

The Ertsberg mine, controlled by Freeport Minerals, is on an 11,500-ft tropical mountain in West Irian, Indonesia, and began production in 1972 (Joralemon, 1973).

The latest development in the area is Ok Tedi on Papua New Guinea.

1.2. Current Status and Future Trends

TA M. LI AND MARIANNE SNEDEKER

INTRODUCTION

Mining in the United States and elsewhere has undergone an evolution—or revolution—in the past few years, as an economic depression set in. In 1981 the iron ore operations were the first to be affected with the impact hitting the nonferrous industries in the following years. Mines closed, personnel were let go, and those operations still continuing began to tighten their belts.

The period 1983-1986 was characterized by low metal and mineral prices. Efforts to control production costs were characterized by improved mine production, better equipment utilization, and closer cooperation between labor and management. Concessions on wages were the key to the restartup of mines such as the Butte, MT, copper pit (Bohnet, et al., 1987).

In the same period (1982-1986) a bright spot was precious metals mining that has seen an upsurge in operations and new properties, particularly in the US and Australia. New mines and/or the expansion of existing operations kept coming on stream. Just recently, Newmont Mining, American Barrick, and Echo Bay announced an enlargement of their gold resource base and Asamera Minerals in Wenatchee, WA, disclosed an extension of the reserves adjacent to the Cannon mine.

As an inevitable consequence of the trends in the mining industry, the *bottom line* profitability of the major metal industries has eroded seriously. According to US Dept. of Commerce data, the steel industry has recorded a net loss in each of the last five years and total losses over the period amount to \$12.5 billion (Sousa, 1988).

The corresponding losses of the nonferrous metal industries (e.g., aluminum, copper, and lead), while not as staggering as those of steel, have also been extensive. Collectively, the US nonferrous metal producers lost money in each of the four years between 1982 and 1985. Reflecting the major restructuring that has occurred in the nonferrous metal business over the last several years, however, this sector returned to the black in 1986 and registered a \$760 million profit. Profit and loss trends in the metal industries in the period 1980-1986 for ferrous and nonferrous metal production are shown in Fig. 1 (Sousa, 1988).

By 1986 and more significantly in 1987, the economic condition of the nonferrous metals industry improved as commodity prices rose. The companies that survived had become "lean and mean," with drastic changes in the management style of their operations. Favorable negotiations with the mining unions, especially in Arizona and Utah, also contributed to this economic recovery.

PRODUCTION

The production index of the domestic metal industries when compared to the rest of the US economy show how these industries have underperformed the economy as a whole. Using 1977 as the base year, the Federal Reserve Board's (FRB) production index (Fig. 2) for the industrial sector of the economy as a whole increased by nearly 25% through 1986, while primary metal and metal mining indices declined by 24% and 28%, respectively, in the same period (Sousa, 1988).

Comparison of the FRB's production indices provides insight into another fundamental factor behind the recent decline of the metals industries: the US economy simply appears to be working smarter, making more by using less (Sousa, 1988).

Declining production and capacity utilization together with the compelling need to lower labor costs in order to become more competitive have had a devastating impact on the employment rolls of the metal industries. For example, total employment in the metal mining industries at the end of 1986 was approximately half what it had been less than a decade earlier, Fig. 3 (Sousa, 1988).

Metallic and Nonmetallic Production

Tables 1 and 2 show the material handled at surface mines in the United States by type and commodity. Table 3 lists the 25 leading metal and the 24 industrial mineral surface mines in the US in order of crude ore output (Tanner, 1988).

Coal

Of the 50 largest bituminous and lignite mines in the US, 38 are surface operations. Production data for these mines in 1986 are given in Table 4 (Anon, 1987).

In 1986 surface coal mines produced 496 Mt (536,444,000 st), 60.4% of the coal produced in the US. In 1985, 167,009 persons were employed in surface coal operations and worked an average number of 208 days. Production per man day was 3.9 t (4.32 st) (Anon., 1987).

Table 1. Material Handled at Surface Mines in the United States, by Type (Million Short Tons)

PRODUCTIVITY

According to the US Dept. of Labor statistics, a total of 93.7 million employee-hours (man-hours) were worked at metallic mineral operations in the United States in 1984. Of those, 47% were in mining, 2% in independent shops, 39% in processing, and 12% in offices. During the same year, 73.6 million man-hours were used at nonmetallic mineral operations, of which 35% were in mining, 51% in processing plants, and 14% in offices. At all coal operations, 363.4 million man-hours were worked in 1984, comprising 84% in mining, 1% in independent shops, 10% in processing plants, and 5% in offices (Nilsson, 1987).

The average US open pit productivity in the decade 1975-1985 is shown in Fig. 4. Productivity in processing plants has remained relatively constant during the decade but in 1984 reached an average of 11.8 t (13.0 st) of crude ore per man-hour. There are, of course, large differences between types of ore. Iron ore requires grinding, separation, and pelletizing. Copper, lead, zinc, and other ores normally require grinding and flotation (Nilsson, 1988). Coal may simply require washing or more sophisticated flotation and separation processes.

The average productivity in US metal and coal mines surface in 1984 is shown in Table 5 (Nilsson, 1987). Productivity in US surface coal mines by size of mines is shown in Table 6 (Nilsson, 1987).

TECHNOLOGICAL DEVELOPMENTS

Precious Metals

The level of precious metals prices, and particularly gold at about \$400 an ounce and higher, has resulted in an explosion in exploration and surface development activities. Innovative technology has been the utilization of hydraulic shovels, continuous mining systems, computer-assisted pro-

duction control and scheduling, and improved bulk materials conveying and handling (Bohnet, et al., 1987).

Industrial Minerals

Development has been at a brisk level. There have been efforts to incorporate more mine planning and scheduling techniques to improve productivity. Long-term development plans have been devised. Through the use of PC-based computer software systems, smaller operations, in particular, have a greater degree of engineering capability (Bohnet, et al., 1987).

Fig. 4. Average productivity in US surface mines (Nilsson, 1988).

Heap Leaching

A technological development introduced in the late 1960s, heap leaching, has made significant contributions to the viability of precious metals operations, both for low-grade deposits and the reworking of old properties.

Although the principles of heap leaching have a long history (mines in Hungary recycled copper-bearing solutions through waste heaps in the mid-16th century and Spanish miners percolated acid solutions through large heaps of oxide copper ore on the banks of the Rio Tinto about 1752), the first commercial application of the technology occurred in the late 1960s at Carlin Gold Mining Co. in Nevada (van Zyl, et al., 1988).

It is in the past ten years that heap leaching has developed into an efficient method of treating oxidized gold and silver ore. It has proven to be both an efficient way to extract precious metals from small, shallow deposits, as well as an attractive way to treat large, low-grade, disseminated deposits (van Zyl, et al., 1988). The technology is also being used to recover the metal values from waste dumps at old mining properties.

The results of the technological improvements which have occurred throughout the 1970s and 1980s can be seen in the dramatic production level increases. By 1986 production of gold from heap leaching had increased to over 30% of total US gold production from an estimated 6% in 1979 (van Zyl, et al., 1988).

[‡] Includes industrial sand and gravel. Construction sand and gravel were not available for 1985 because of biennial canvassing.

EQUIPMENT TRENDS

A most important development in surface mining in recent years has been the use of increasingly sophisticated on-board electronics and microcomputer systems for mining equipment. These systems range from those used to assist the personnel who is operating the hydraulic shovel or walking dragline to managing and monitoring the performance

and productivity of the mine's mobile equipment (Tanner, 1988).

There has been over the past few years a very slow yet steady shift to electric power for mining vehicles. However, because of the high mobility and portability of diesel-powered vehicles, the diesel will probably continue to be preferred in the foreseeable future (Tanner, 1988).

Large shiftable mining equipment will be necessary in

the future as mining of deeper near-surface deposits becomes necessary. This will be particularly necessary where climatic conditions are extreme or overburden removal is difficult. An example is the Captain mine in Illinois where coal is transported by truck, but land is reclaimed by moving the overburden and topsoil by a conveyor system designed to handle 2.6 km³/h (3366 cu yd per hr) (Tanner, 1988). The development and application of high-angle, elevating, and cross-pit conveyors result in considerable reductions in transportation costs. Conveyors are an alternative to trucks and other diesel-consuming transport. The cable belt conveyor system has undergone considerable design changes, improvements in performance and reliability, and operating costs (Singhal, et al., 1987).

The best features of trucks and conveyors can be combined by using an in-pit crusher. These can be fully mobile, semi-mobile, or fixed crushing plants. One advantage is to reduce material to the size limit transportable by conveyors (Singhal, et al., 1987).

Draglines that are crawler-mounted have resulted in reduced time and cost of erection. A major development has been the availability of long-boom draglines (Bohnet, et al., 1987; Singhal, et al., 1987).

Another development has been drill rigs with computer-based programmable controllers (Bohnet, et al., 1987).

Availability of suitable transmissions for large mechanical drive trucks has been an improvement in off-highway trucks. Other significant developments include renewed interest in trolley-assist, truck dispatch systems, higher horsepower, and greater capacity (Singhal, et al., 1987).

Continuous surface miners have been developed that incorporate a rotating cutter drum and conveyor discharge system (Bohnet, et al., 1987). Such surface miners are es-

pecially applicable to multiple seam mining where the seams are separated by thin bands of overburden or in cases where seams are split and where materials of different qualities must be separated. Surface miners can mine to very narrow limits, improving resource recovery and providing an uncontaminated product (Singhal, et al., 1987).

Hydraulic excavators are competitive with small to medium-size cable shovels and wheeled front-end loaders, especially in smaller open pits such as those in many of the new gold operations (Bohnet, et al., 1987).

Manually controlled bucket wheel excavators are relatively inefficient. A number of suitable microprocessor-based bucket wheel automation systems have become available. There is also a shift toward the all-hydraulic compact bucket wheel excavator (Singhal, et al., 1987).

Scrapers, front-end loaders, and electric cable shovels comprise the traditional loading equipment for surface mining. All classes of conventional loading equipment have undergone design changes, including improved electrics and incorporation of health monitoring and diagnostic systems. These changes are resulting in increased reliability, improved performance, and a lower unit cost of production (Singhal, et al., 1987).

Dredging is an attractive means of lowering mining costs, particularly in gold operations. Dredges are currently in use in Alaska, Ecuador, Brazil, Colombia, and Papua New Guinea (Bohnet, et al., 1987).

Especially in large surface mining operations, adequate communication has been a problem. On-board radios and computer equipment are focal points for improved communication and control and mine haulage efficiency (Bohnet, et al., 1987).

Other recent developments in surface mining technology include the wider use of emulsion-type explosives and developments already mentioned: increased use of hydraulic excavators, use of in-pit crushers, and shiftable belt conveyors (Tanner, 1988).

FUTURE TRENDS

Responding to increased competitiveness, the future of surface mining has become a showpiece for technological innovations to meet sharply rising production costs. In the period of depressed commodity market prices, surface miners responded through the aggressive application of technology created by developments in mechanization and computers. In establishing a solid pattern of cost consciousness for mine productivity, future trends will see even greater mine productivities as a result of innovations in:

- Off-highway truck design and performance.
- Hydraulic shovel reliability and durability.
- Computer-aided controls in mine operations and design.
- Blasting agent utilization and detonation efficiencies.
- Management planning and manpower scheduling and utilization.
- Continuous mining and materials handling systems.

In closing, surface mining will continue in the forefront of innovation, mandated by the industry's commitment for excellence in cost competitiveness and requirements for meeting world material demands.

Exploration and Geology Techniques

Richard L. Brown, Editor

2.1 Overview of Exploration

RICHARD L. BROWN

In this chapter a number of authors describe the kinds of geological thought and exploration techniques applicable to the original identification and subsequent mensuration, in terms of tonnage and grade, of mineral deposits judged by the geologist to be suitable for surface mining. Many of these techniques are also applicable to *grass roots* or systematic reconnaissance style exploration. It is appropriate that there be discussion of reconnaissance techniques in this handbook since that activity in established mining districts often continues long after initial production.

Exploration geology seems to have separated, as a discipline, from mining geology, not because the one group has a greater or less need than the other to know and understand all these techniques as much as that each group has different objectives. The mining geologist seeks new veins or other new extensions to ore bodies and expects to find these on a regular basis, whereas the exploration geologist must find new districts and knows that he will be lucky if he makes one or two such discoveries during a career. The mining geologist assists in the day-to-day problems of production, and reacts to the discipline which accrues to achieving daily and monthly goals. The discipline accruing to the discovery of a new mineral deposit in a new district is of a different sort. At any rate, the separate disciplines of exploration geology and of mining geology merge at that point in the history of a mineral deposit, after discovery while it is being explored and determinations are being made of the tonnage and grade—that is to say, the period in the history of an ore deposit when data necessary for a feasibility study are being prepared. Because so many of the techniques discussed in the following pages apply both to the general reconnaissance-type exploration and to the business of *drilling off* an ore body, the authors have been rather general in their treatment of the various forms of exploration geology which apply to the commodity they have discussed. In this introductory section, exploration techniques common to most commodities are addressed with the purpose of providing an overview of the duties of the exploration geologist as he takes a prospect from discovery to the final economic estimates.

A review of the technology directed at the search and discovery of economic mineral deposits illustrates once more that there is “nothing new under the sun.” There has been a continuum from medieval times to the present day of man’s knowledge of mineral deposits and of ways of finding them. A quick trip across Europe shows that the Phoenicians, Greeks, and Romans were all adept at reading gossans, at panning heavy minerals from stream sediments, and at a

variety of other exploration techniques still used by today’s geologists. It is also obvious that these ancients had more than a rudimentary grasp of many principles of economic geology.

The search for ore begins with the development of ideas as to where the search should be conducted. Application of the most modern geophysics, geochemistry, remote sensing, and other techniques cannot be made until the geologist has decided where the search should begin. The first things a geologist must decide are what the ore body he hopes to find looks like, what minerals are contained therein, and how it was formed. He must, in short, develop an empirical model before he leaves his office and goes to the field.

Most of the ideas, a few examples of which are described below, geologists use now and will use during the foreseeable future had been published by 1974. In March 1965, The Canadian Institute of Mining and Metallurgy held a symposium on volcanogenic deposits. The papers given at that symposium, published by the CIM later that year, form the bible used by most geologists as they plan their exploration for volcanogenic deposits. John Guilbert and David Lowell published their paper on “Mineral Zoning in Porphyry Copper Deposits” in *Economic Geology* during 1970. The so-called *Red Sea* book (*Hot Brines and Recent Heavy Metal Deposits from the Red Sea*, edited by Degans and Ross) was a 1969 publication. The term *plate tectonics* was firmly in place by 1970, and the *Journal of Geophysical Research* published its compendium of papers related to that subject in 1973. Kambalda in Western Australia was discovered in 1968, and the recognition that some nickel-copper deposits were derived from ultramafic volcanic rocks was made in print by a number of authors in the very early 1970s. Our knowledge of the so-called Mississippi Valley deposits lags far behind some of the other ore types mentioned above, but the sum of our knowledge of these deposits is pretty much contained in the August 1971 issue of *Economic Geology*.

The search for volcanogenic ores, many of which are mined from surface, has widened possibly further than any other type of exploration, and it may be well to describe the model which governs much of that exploration. In brief, the geologists who participated in the Canadian symposium in 1965 had noted that descriptions of synvolcanic and syngenetic ores described by German and Japanese workers corresponded closely with the results of our own mapping and observations of the Precambrian deposits in Northern Ontario and Quebec. As a result of this mapping, they were able to demonstrate that many of the Canadian deposits had

been formed on ocean floors, apparently from brines derived from highly siliceous rhyolite domes. In addition, iron-rich silicate deposits often spread far from the volcanic dome and were deposited on the sea floor over wide regions. Thus the three elements of the volcanogenic model were: (1) the volcanic dome containing imbricate stringer zones; (2) the polymetallic sulfide deposits, formed on the ocean floor; and (3) widespread cherty pyrite bed. The complete system was usually covered by more recent volcanic rocks, often andesite or basalt. Thus the subsequent direction of massive exploration money at the andesite-rhyolite contacts in many shield areas throughout the world.

It would be difficult to pinpoint the decade during which geologists routinely began to map the distribution of clay alteration products around porphyry copper sulfide systems. A quick glance through bibliographies shows a number of papers on the subject were published in the 1930s. A number of company geologists were mapping such patterns routinely during the early 1950s. A number of papers authored by such people as S. C. Creasy, Richard and Courtright, and Paul Kerr demonstrated widespread interest in the subject during that decade. During the 1960s, Guilbert and Lowell, collectively and individually, published the results of their observations of alteration patterns in the southwest United States and in some other areas as well, and their 1970 paper cited earlier is now regarded by most North American geologists as the standard text on the subject. There is presently very little porphyry copper exploration near established mines or in new districts conducted which does not respond to the Guilbert and Lowell model.

Recently, it has become clear that predictable distribution of minerals containing fluorine, barium, and other elements, occurs around the previously known stacked intrusive complexes which host the molybdenum-porphyry systems. The discovery of molybdenum at Mt. Emmons in Colorado and at Pine Grove, Utah, can be attributed to recognition of this mineralogical distribution. Other important exploration programs, generated by recognition of similar features in other areas in the western United States, are in progress.

However, no such conclusive models have been developed for the Mississippi Valley deposit. While there is an excellent body of literature which describes most of the deposits in the six or seven type localities scattered around the United States and Canada, there is no single body of observations or of theory which is accepted by the majority of the workers in the field and which can be described as a common denominator underlying exploration activity. There is a need for additional work directed at these Mississippi Valley-type deposits.

It would appear that geologists engaged in the exploration of these deposits are paying increased attention to the study of paleosurfaces and paleoecological environments which are dominated by carbonate-rich rocks. Of course, the internal characteristics such as collapse breccias, limestone-dolomite interfaces, and recrystallized dolomitic rocks are recognized and mapped, and trigger intense exploration when they are seen. Possibly there is some consensus that the margins of carbonate platforms are good places to look for these deposits, and in southeastern Missouri, criteria implicit in both the old and new leadbelts are carefully adhered to.

Also, there is no commonly accepted rationale governing exploration for replacement-type polymetallic sulfide occurrences hosted by carbonate rocks. Possibly researchers and explorationists had not been interested in this group of hydrothermal ore deposits because they are relatively rare, and the metal content, dominated as it usually is by lead and

zinc, is apt to be relatively low and unremunerative. The Mexican deposits such as Plomosas, Santa Eulalia, Naica, Charcas, Providencia-Concepcion del Oro, Taxco, San Martin, La Encantada, Fresnillo, and Velardena are not well known, and the results of significant research, if any has in fact been conducted, are proprietary and locked up in mining company reports. Probably the most utilized lead in the search for these deposits is directed in the vicinity of veins and veinlet systems which can be classified either as feeder-type mineralization of the replacement bodies or as leakage from them.

The search for nickel-copper deposits during the 1950s and 1960s in general contemplated a Sudbury-type model in which it was supposed that a sulfide magma body had been injected from depth to a near surface position by any of a number of proposed mechanisms. The Sudbury, Ontario and the Thompson Lake, Manitoba districts both lie in the join between contiguous provinces of the Canadian Shield, and it has been widely assumed or hoped that additional deposits can be found along these sutures and supposed zones of weakness. Substantial exploration time and dollars have been expended in the search for deposits in these zones, and still continues, although on a much more limited scale. However, as noted earlier, subsequent to the discovery of nickel in the Kambalda district in Western Australia, it was recognized that some nickel-copper deposits are associated with ultramafic volcanic flows. The Travis and Wodell paper, published in the proceedings of the 12th Commonwealth Mining Congress, and A. N. Naldrett's paper entitled "Nickel Sulfides, Classification and Genesis," published by the CIM in 1973, each described this association. Nickel exploration has been at a low ebb during the last decade, due to unremunerative prices received by producers for that metal, but such nickel exploration work as does proceed is directed at both magmatic and the volcanically derived sulfides.

During the past 15 years, fair consensus at least regarding the morphology, if not the genesis, of uranium deposits hosted by sandstones and by quartz pebble conglomerates, has been achieved. Exploration, designed to test sulfide-rich as compared to oxide-rich portions of appropriate sandstone and quartz pebble conglomerate units, has developed. However, no such consensus has been reached in respect to the *vein-type* deposits of northern Saskatchewan or of northern Australia. These deposits appear to be characterized in both locations by high-grade pitchblende *veins* hosted in crystalline or in metamorphic rocks, covered by Proterozoic sediments in which are bedded carnotite or carnotite-type mineralization. While there is very little agreement amongst geologists as to how these deposits are formed, most organizations involved in the search for these deposits appear first (mainly by means of airborne electromagnetic and radiometric surveys) to search for signs of the bedded material in the overlying sandstones, and then to attempt to search for the veins.

Geologists who concern themselves with exploration, evaluation, and production of the various industrial minerals, as well as those involved in coal, oil shale, tar sands, and other similar materials, are obviously as interested in the genesis and geological environments of these deposits as are the hard mineral geologists. However, in most cases the deposits are huge and relatively easy to find and therefore the difficulty and cost of original discovery have not been as great as they have been in the case of the commodities discussed previously. The major challenge in the case of the industrial minerals, and in the case of the hydrocarbons, has been identifying major volumes of material which conform to various engineering and chemical standards. Therefore

these geologists think not so much in terms of origin and empirical models, as they progress in their exploration work, as they do of quality control and engineering parameters.

The importance of these models, of course, is that they provide terms of reference and criteria to the geologist as he decides, for example, whether or not a given district or prospect warrants more expenditure. If the geologist maps a considerable number of features which conform to his model for a given deposit type, he may well decide to recommend drilling or some other form of physical exploration. If, on the other hand, his data shows that few of the elements of his model are present, he may decide that additional expenditure is not necessary or wise. Similarly, the geologist might use his model to tell him in which direction, either laterally or vertically, additional drilling should be planned. If he knows that the features he is mapping are usually found vertically above another feature of economic importance, he may decide to recommend deeper drill holes. The models, above all, give the geologists terms of reference and continuity of information which extend beyond the bore of the drill hole he is considering, and beyond perhaps, the geometry of the ore shoot being investigated.

The discovery by Newmont Mining Company of the Carlin gold deposit a decade or more ago generated a substantial amount of precious metals exploration in the basin and range province of the western United States. The primary exploration technique involved in this search has been the collection of samples, both geochemical and rock samples, which are assayed for gold, and a variety of other elements, such as mercury, which are thought by the geologists involved to be useful "indicator or pathfinder elements." This search often requires a collection of samples from wide areas, without much geological discrimination. Recently, emphasis has been placed on hot spring environments, the so-called jasperoid environment; the interest in this type of environment being generated by recent discoveries at Alligator Ridge, Nevada, and in the Caldera environment, similar to the one at McDermitt, Nevada, where mercury mineralization has been mined for some time.

In summary, it should be reiterated that as mineral exploration develops and grows more sophisticated, increasing care will be given to the development of the *empirical model*. The model is simply a generalized amalgam of features of known deposits, the enclosing host rocks, and all the various alteration patterns which are usually attendant to the mineralization. Once the model is produced and agreed upon by everyone involved, the next exploration step is to decide which geological province might provide all the various factors and features in the model. The third step is to identify, through literature searches and through inspection of old exploration records and other geological material, where within the district chosen the various features called for by the model might be found.

Prospectors as well as modern explorationists have always had models in mind. In former years the prospectors looked for signs of direct mineralization in outcrop, and proceeded then to test these outcrops by drilling or other means. The modern explorationist still hopes to find mineralization in outcrop, and on occasion will do so for many years hence. However, increasingly his work will consist of testing models, once he has found areas in the field which conform in most respects to the model.

Mining company managements, increasingly, will have to get used to the idea of drilling concepts or models rather than mineralized outcrops. One management which has already adopted this idea is that of Western Mining, the Aus-

tralian company. D. W. Haynes, its copper consultant, has explained in his paper entitled "Mining Technology in Mineral Resource Exploration" (published in *Proceedings, Third Invitation Symposium on Mineral Resources in Australia*, held in Adelaide in October, 1979 by the Australian Academy of Technological Sciences) how Western Mining geologists put together source rock theory with known information regarding the sedimentary basin on the Stuart Shelf to find the Olympic Dam deposit. The Western Mining geologists, Haynes explains, were looking for areas in the sedimentary basin in the state of Southern Australia where sediments similar to those hosting the Zambian Copper Belt might be found in proximity to basaltic rocks. In addition, a preconceived tectonic model was apparently postulated, and a lineament analysis, aided by data derived from Landsat images, was produced. Once the complete model had been settled upon, it was aggressively explored, and the important Olympic Dam copper-uranium discovery was made. Haynes points out that the mineral deposit which was discovered was not precisely the same type as was anticipated and this perhaps provides some food for thought. The Olympic Dam discovery is obviously not the first successful application of modeling. It is, however, one of the better documented cases of successful exploration generally designed to test a model.

Geological reasoning has improved and must improve even more if an adequate rate of discovery of mineral deposits is to be maintained. There has been parallel improvement of various geophysical, geochemical, and remote sensing techniques. Geophysics has progressed from Thomas Edison's dip needle, successfully used at Sudbury, Ontario, early in this century, to satellite-mounted magnetometers. Geochemistry has progressed from the practice of early Scandinavians, who during the Middle Ages chased mineralized boulders up streams of glacial debris to their source to determinations of 25 or more metals in soil samples. Remote sensing, in its strict sense, has been developed from the day prior to the Second World War when Canadian geologists made interpretations from oblique aerial photographs to today's interpretations made from enhanced remote sensed images from satellites.

Interpretation of leached outcrop and of gossan, which was started by Augustus Locke and Rowland Blanchard in the 1920s and carried on, among others, by Kenyon Richard and Harold Courtright in the 1940s and 1950s, appears to be a dying art, simply because surface mapping of large porphyry copper systems is not now an everyday activity. However, during the 1960s, enhanced evaluation of potential drill targets was made possible by the interpretations of clay alteration patterns combined with that of leached cappings. The gossans in Western Australia are far different from those of the western United States, but an awareness of the technique and a fair ability to apply it to gossans in that country occurred. Later the Australian expertise was transferred to South Africa, and a number of discoveries were made there as well.

Prototypes of much of the geophysical equipment in use today were in field prior to the Second World War, for example as previously referred to, Thomas Edison's dip needle, with which he discovered or, at least almost discovered, continuations of the nickel-copper ore at Falconbridge in the Sudbury District. Hans Lundberg, using an equipotential method which verged on electromagnetics, made a great discovery at Buchans Newfoundland, in 1926. Technology developed for military purposes during the war was put to work immediately thereafter, principally in the development of electromagnetics and of airborne electromag-

netics. Geiger counters, rarities before the war, become commonplace shortly thereafter. In the mid-fifties, relatively trouble-free ground electromagnetics systems were used routinely in the field and torsion spring magnetometers also were developed; these instruments dramatically increased the rate at which readings could be taken. Airborne electromagnetics and magnetics also became routine during the early 1950s. The combined use of these two techniques resulted in a very impressive string of discoveries, mainly in Canada, which continued at least until 1975. In recent years the rate of discoveries by AEM and AM has declined, for a variety of reasons. However, one can wonder if the application of a single technique will ever again result in a list of discoveries such as Thompson Lake, Manitoba; Heath Steele, New Brunswick; Mattagami and Joutel, Quebec; Timmins, Ontario; Sturgeon Lake, Ontario; and Crandon, Wisconsin. This list, while incomplete, represents an extraordinary record of discovery. Also, in the mid-fifties, Dr. Arthur Brandt completed development of the induced polarization method. The Geiger counter largely gave way in the 1960s to the scintillometer. Drill hole logging by regular radiometric methods became commonplace in the search for roll front uranium deposits in sandstones, particularly in the western United States.

The advent of various microelectronic devices has given geophysicists the capability of gathering enormous amounts of data. For example, modern airborne electromagnetic equipment provides as many as six audio frequency channels, two very low frequency electro EM channels, four gamma-ray spectrometer channels, and a magnetometer channel. All 13 channels are recorded on magnetic tape every half second.

The proton magnetometer can now achieve a sensitivity of about one gamma. High sensitivity magnetometers are used for identification of extremely subtle features in areas of very low magnetic relief. Airborne spectrometer surveys, utilizing 49 161 cm³ (3000 cu in.) crystals are now routine. These crystals yield much higher count rates than has been the case; the differentiation between earth generated radiation and atmospheric radiation is measured separately and identified.

Of course all the additional information collected by the newer equipment has provided enormous challenges for the interpreter of the data. Sulfide sources are easily confused with nonsulfide sources as much these days as previously.

In spite of improvement of the equipment, it has not yet been possible to make significant improvements in the depth penetration of electromagnetics equipment. During the past five years, transient electromagnetic and audiomagnetic telluric systems, the latter utilizing either distant thunderstorms or nearby controlled sources, have come into use. This system reputedly can achieve depth penetration of several hundred meters. Presumably additional research as to the application of these systems to mineral exploration problems will continue.

Additional research and improvement of in-hole electromagnetic and induced polarization systems will continue. Most current interest appears to be directed at fixed source time domain units, fixed source continuous wave multifrequency units, and single frequency moving transmitter-receiver systems.

The broad range of portable gamma-ray detectors employed in airborne radiometric surveys is also adapted to in-hole surveys. It is anticipated that improvements in simple nondiscriminating scintillation counters for channel differential spectrometers will be made.

In summary, geophysicists have been able to make re-

markable improvements in the portability and accuracy of their equipment. They have not been able to make substantial improvements in the depth penetration of the equipment because increased depth penetration means increased volumes of rock energized and therefore increased numbers of nonsulfide features which can cause responses and consequently signal noise with concurrent difficulties in interpretation. Because as many mineral deposits remain to be found at depths beyond the reach of present geophysical equipment as have been found in the near surface, we can confidently expect that additional research and development of equipment capable of seeing deeper into the earth will continue.

The basic principles of geochemical prospecting have been known for thousands of years. They were in fact successfully applied by early prospectors who traced visual indications of ore dispersion patterns in rocks, soils, and stream sediments back to bedrock sources. However, it was not until the 1930s that chemical emission spectrographic analytical methods began to permit trace element measurements. The Russians and Scandinavians began to use geochemical exploration techniques, as we know them, prior to the Second World War. Subsequent to the war, an explosion of geochemical exploration activity occurred, permitted by the development of inexpensive rapid colorimetric analytical techniques by the United States Geological Survey. Research activity spread to the United Kingdom and thence to other countries in western Europe during the 1950s. Students of Hawkes, Webb, Bloom, and Warren took the technique into almost every part of the world and many discoveries were made. As surveys were completed during the 1950s and 1960s, the various ways by which elements can become dispersed throughout the secondary environment became fairly well appreciated. During the 1970s startling advances, again made possible by the advent of microelectronics, were made in the analytical end of geochemical exploration. Atomic absorption instruments and techniques were refined and matrix corrections introduced as routine procedure for certain elements. X-ray fluorescence methods were greatly improved. Plasma spectrometry permitted significantly low detection limits for a number of elements. This improvement in analytical quality and reduction has resulted in a marked decrease in the dollar cost of exploration. Computer data handling capability has kept pace with analytical advances. Computerized data plotting as well as univariate and multivariate statistical procedures are widely accessible.

Many have pointed out that the improvement in equipment has not been matched by comparable improvement in the understanding of fundamental geochemical processes. Routine surveys have been laid out and interpreted without regard to the solid body of information which has been collected. Hopefully, future practice will catch up with the theory already in place.

The geologists also have improved hardware at their disposal and increased availability of this equipment should result in an increased rate of discovery. The microprobe is probably the most important of this new equipment. The ability to detect variations in metal content in individual minerals collected from various parts of districts and of mineral deposits will greatly increase the geologist's ability to predict projections and to site exploratory drilling and other exploration activity. Increased use of the fluid inclusion stage will result in increased knowledge of fluid inclusions and of hydrothermal fluid temperature, pressure, and composition which is not unknown in respect of many mineral deposits. Collection of this fundamental knowledge will result in better definition of mineral zoning patterns and will, as a result,

guide exploration. Fluid inclusion research will become a routine part of modern mineral exploration.

The microprobe will make it possible to determine phase compositions of sulfide-silicate vein and wall rock assemblages. These studies also will assist in determinations of deposit zoning and increase reliable predictability of exploration parameters. Sulfur isotope studies will also become routine and will assist in the classification of ores and the placing of these ores in appropriate models.

Application of nearly all the techniques listed in the previous pages will result in the production of enormous amounts of data. At present, geologists use computers to store data and make various calculations as to tonnage, metal content, and economic viability of mineral deposits, but they have not found a way to utilize the deductive capabilities of computers to find deposits. Possibly they never will, as the human brain is still the best computer of all. However, it is obvious that increased research as to the application of computer techniques to exploration will continue.

In due course geologists will be able to make much better use of images produced by sensors placed in satellites than they now do. Much of the science and technology required to produce images which will identify various rock types now exists. These sensors have been flown from time to time in U-2-type aircraft, and experimental surveys such as famous ones over Saindoc, Pakistan, and Goldfields, Nevada, as well as the various case histories flown by a GEOSAT-NASA joint experiment, provide impressive data. It is clear that the potential impact on mineral exploration of remotely sensed data will be significant.

The ultimate exploration tool is still the diamond drill. We have seen substantial improvement in the reliability, portability and, most important, the percentage of core recovery achievable by drilling equipment in the past few years. The retrievable core barrel has been a great cost saver. However, costs of drilling in the past decade have increased drastically, and the mining business needs, and needs soon, additional improvement. Probably the next routine improvement will be the retrievable bit. If some way can be found to change drill bits without removing an entire string of drill rods, important savings will be achieved. It is certainly to be hoped that the drilling industry will continue its search for ways in which it can keep the costs of diamond drilling under better control than is now the case.

Both the exploration geologist and the mine geologist must at all times have a reasonably accurate perception of the economics of the project. It goes without saying that this perception of economics should apply at all stages of a project and will be applicable initially when a grassroots or reconnaissance program is devised. If a discovery is made in a new district, even during the very early stages of the assessment of the prospect, the geologist must make a back-of-the-envelope calculation designed to demonstrate that under prevailing and under forecast economic conditions, presuming that all assumptions as to tonnage and grade materialize, the mineral deposit he is modeling, will yield a suitable return on investment. During the early stages of such a project, there are few hard facts and many assumptions. As first order drilling, designed to determine the outlines of the deposit continues, these assumptions are replaced by facts, and estimates become more reliable.

A second occasion for an economic review of the project might reasonably occur when plans are made for the expensive closely spaced drilling required to determine final tonnage and grade figures. This estimate, of course, will utilize

many assumptions but substantial data will have been provided by the drilling completed. A crude estimate of tonnage and grade will be available, metallurgical data (supplied by bench tests on material from drill cores) will be on hand, assumptions concerning mining costs will be made possible, if only by comparison with other similar operations. Sufficiently accurate assumptions concerning the amount and cost of infrastructure can be made, and the cost of any necessary access roads and other similar items can be reasonably estimated. Presumably this estimate will be made by a team of construction and mining engineers, assisted by the geologist who should be on hand to provide data and interpretation of data concerning the nature and characteristics of the ore deposit, including among other things, continuity of grade, mineralogical zoning, and varying characteristics of host rock type.

There are, of course, various levels of economic estimates, leading from the first preliminary calculations to the full-scale detailed estimates as to the cost of a given project. In Fig. 1, various levels of economic estimates are defined. Probably, for reasons which will be explained later, the exploration geologist should be substantially involved during the early planning of a project, at least in those phases which involve mine design and planning. In the later design and planning stages, which involve mainly detailed estimates of construction, the geologist will be much less involved, but should in any case be available to the design and planning team until the mine opens.

If the results of the feasibility study described in the preceding paragraphs should indicate that a deposit will be financially attractive (should assumptions concerning both tonnage and grade be later confirmed), the next obvious step is to cost out the kind of detailed drilling program necessary to generate accurate ore reserve estimates. The most important consideration in this regard is drill hole spacing. This is a critical matter, as the cost of the drilling can be (even in, say, the case of only a medium-sized porphyry copper deposit) on the order of \$10 million or even substantially more. However, as the preproduction expenditure in the case of such a deposit would run into hundreds of millions of dollars, it can easily be recognized that the cost of diamond drilling and sampling of drill results is a very poor place to try to save money. On the other hand, the geologist does have a responsibility to recommend a program which will adequately sample, but not overdrill, the prospect. We would all like to think that it should be possible through the application of some statistical formula or other to precisely establish optimum drilling spacings. Sadly, this is not the case. In many districts long practice may have established the proper drill hole interval, but many of the mineral deposits being discovered during the 1980s are in new districts, and some involve types of mineral deposits for which no precedents are available. Obviously the first matter to be considered in reaching such a decision is a variation of the metal content from hole to hole in the drilling already completed. If there is a small variation, then obviously the drill spacing can be much larger than in the case where there has been large variation of metal content.

Another matter to which the geologist must give his most careful consideration is sample size, or the length of core which will be included in each sample to be sent for assay. Assay costs in case of even a medium-sized deposit will be astonishingly large, and if, for example, the decision is reached to sample every 3 m (10 ft) run of core, rather than each 1.5 m (5 ft) run of core, these very large numbers can

Fig. 1. Definitions of various levels of economic estimates (prepared by A.O. Marsh, Jr., Central Engineering Dept., ASARCO, Inc.).

be halved. Here again, the optimum choice will result in the least expensive alternative which will completely achieve the required results.

Other decisions, such as staffing, choice of assay office facilities, core storage, provision for constant, high-caliber geological input, and interpretation of data on a current basis are all highly important matters to be costed into the final total budget. There is temptation to scrimp on all of the above-listed matters, but inadequate attention to any of them can in the long run be very costly.

Aside from making the proper arrangements as to drilling intervals, sampling intervals, standards of assaying and the like, there are many other matters which need to be considered. Large volumes of core will be coming in from the drill sites each day. Good facilities will be needed for logging, photographing, and storage of the core; splitting or sawing, and preparing the samples for assay is no small job. Literally hundreds of assays will be returned and of course these assays will need to be plotted and posted on the appropriate maps and sections on a current basis.

As a result of the necessity to perform all the tasks listed on a current basis, there is also need to provide for housing and eating facilities for as many as 30 or 40 people. Supervision must be provided not only for the geological end of the job but also for the logistical end. It is important to reiterate that the final authorization for expenditure should be constructed from costs carefully computed from realistic assumptions, and the recommended procedures should be completed as inexpensively as possible. However, reductions in costs that result in the production of poor samples and

poor interpretation can lead, at the very least, to severe cost overruns of the finally completed exploration job. And worst of all, if, as occasionally has happened, it is discovered after the mine has been opened that the ore "was not there," the entire preproduction cost has been wasted.

Obviously, the end result of the entire exercise is the production of an ore reserve. The geologist in charge of the project will ultimately have to certify the reserves since the success or failure of the entire mining project is, in the last analysis, dependent upon them. Obviously there are, in the case of any modern mining organization, a number of checks and the exploration geologist will not stand alone in this exercise. However, some one individual eventually is required to *sign-off* on the ore reserve. There are two kinds of numbers which will be generated and the meaning of these two following definitions should not be confused. The first is the mineral inventory. The mineral inventory simply is a listing of the pounds of metal confined within a given volumetric limit. This reserve may be stated without reference to the cost of the extraction. The second number, the ore reserve estimate, it best described by reflecting that ore is often defined as "naturally occurring materials which can be removed from the ground at a financial profit." This estimate must be made in connection with determinations of mining plans, the geometry of the ore itself and of internal waste, and obviously in reference to forecast metal prices.

Of course, the ore reserve estimate is the prime objective of detailed drilling. Secondary objectives include provision of material for metallurgical testing, rock mechanics information, and of course, the best possible determination of the

geology. The determination of tonnage is a fairly routine arithmetic calculation. Practice varies from organization to organization, but it is common to make a measurement of the specific gravity of each run of core. If the metric system is in use, the volume of material expressed in cubic meters is simply multiplied by the specific gravity and the tonnage thereby determined. If the English system is in use, a *cubage factor* must be determined, and the volume of rock, as expressed in cubic feet, divided by this factor.

Determination of grade is a much more complicated matter. Corporate policy may dictate the method to be used, regardless of the type of mineral deposit under study. In the vast majority of operating mines in the United States, a simple polygon system is employed. Under this method of ore reserve calculation, the volume of ore closest to a sample point is assigned the grade of that sample. Efforts are made to design polygons so that the division point between adjoining sample points is more or less equidistant between them. The polygon technique has served many mines well over many years, but it sometimes fails to adequately predict trends within ore bodies which may, in fact, greatly influence grade. If such a condition should be suspected, it might be well to consider some form of moving average method similar to that devised by Dr. J. G. Krieg, the famous South African geologist and statistician. Under this technique, it is possible to assign a value of metal content in an area where there is no sample point, by considering the values of all the existing

adjoining sample points. Sometimes, because all adjacent sample points are considered in calculating the grade of a block, some blocks are assigned higher values than are indicated by a sample point within the block. In extreme circumstances, ore can be extrapolated through a block in which there is a blank drill hole. Some engineers have extreme difficulty accepting a mathematical or statistical estimate which will draw ore grade contours through a blank drill hole. Regardless of their discomfort, Krieg's method or trend surface analyses may be the only way to accurately determine grade.

As previously noted, the geologist must remember in addition to the ore reserve data he must produce, he must also produce data which will aid in such matters as pit design and predictions of wall stability.

It is apparent from the foregoing that the exploration and mining geologist, to be really good at his job, must be expert in a wide number of fields. He must know geology and must be current in new geological understanding. He must be a good pragmatic prospector, must understand basic finance and economics, must be good at logistics in order to organize complete drilling and other kinds of exploration projects under his direction. In the following sections various authors describe in greater detail those factors which are important in the geological and exploration work concerned with deposits containing various important minerals and commodities.

2.2 Base Metal Exploration and Geology

J. DAVID LOWELL

EXPLORATION TECHNIQUES

To be suited for surface mining an ore deposit must occur at, or relatively near, the ground surface and must have horizontal dimensions which are relatively large in comparison with its vertical dimension. Stratabound, bedded, porphyry, or enrichment-blanket deposits are typically suitable for surface mining. Experience indicates that in bulk low grade base metal deposits underground block cave mining costs usually become equivalent to surface mining costs when the stripping ratio reaches somewhere in the range of 2:1 to 5:1. Relatively few lead or zinc deposits are suitable for surface mining, but many porphyry copper deposits can be mined by open pit methods, particularly those with supergene enrichment blankets.

A previous section in this chapter has described a number of exploration techniques and applications of techniques. Many of these techniques are applicable both to grass roots and to detailed exploration around known mineral deposits and in established mining districts.

In designing an exploration program to test a deposit in a given district, a number of factors should be considered. These include expected size of ore body, depth, percentage of premineral outcrop, presence of trace element dispersion halos, presence of silicate alteration halos, control of mineralization by structural features, association with certain types of intrusive bodies, association with certain paleo-basin environments, presence of soil or stream sediment anomalies or associated exotic or placer deposits, and physical properties of the deposit which would have a reasonable chance of producing a diagnostic geophysical response.

If the geophysical, geological, and geochemical surveys, which should be designed to accommodate the above-listed criteria, indicate that the showing or known mineral deposit might have commercial dimensions, then diamond drilling designed to determine the physical size of the deposit is probably indicated. If the results of this drilling, which is generally done with AX or BX sized core, indicate that a deposit of sufficient size to be of commercial importance exists, then detailed drilling and sampling should ensue.

SAMPLING AND TESTING

Drilling equipment of some kind must usually be employed to sample all three dimensions of a surface mined deposit. Drill samples usually consist of a split of percussion or rotary drill cutting or a split of drill core made using a core splitter or diamond saw. The whole drill core is sometimes used as a sample with a few pieces of core saved as a skeleton core record.

The drilling method or methods used will be selected considering drilling depths, rock conditions, and the sampling characteristics of the mineralized rocks. Common drilling methods arranged from least to most expensive are as follows:

1. Percussion drilling done from truck-mounted or Air-trac type crawler mounted rigs. Drilling depth is usually limited to about 91 m (300 ft) but can reach 152 m (500 ft) or more. Samples consist of relatively fine cuttings. Sample quality ranges from fair to good in good rock above the water table, to poor to fair in poor rock below the water table.

2. Truck-mounted rotary tricone and down-the-hole hammer drilling using as a drilling medium mud, compressed air, or high pressure-high volume air from a multiple stage air compressor. Drilling depths are usually limited to about 610 m (2000 ft), but with large oil field type equipment very deep holes are possible. Samples consist of fine-grained cuttings which range up to coarse chips when using the down-the-hole hammer in competent rock. Sample quality ranges from fair for mud rotary drilling to excellent for air rotary drilling in good rock at relatively shallow depth. Drill cores are often taken, either as spot cores to calibrate rock identification and sample accuracy, or as continuous wire line core if the rig is equipped for wire line coring.

3. Reverse circulation rotary or percussion drilling. In this system the drilling medium, usually compressed air, is circulated down the hole on the outside of the drill rods and the cuttings are blown back up the inside of the rods. Drill casing is usually carried at or near the bottom of the hole so that contamination of the cuttings sample is reduced to a minimum. Reverse circulation drilling is usually slightly more expensive than rotary drilling but produces a more accurate sample. It is widely used in sampling bulk low grade gold and oxide copper deposits.

4. Diamond core drilling using truck-mounted, skid-mounted, or hand-portable drill rigs powered by gasoline or diesel engines, or electric or hydraulic or compressed-air motors. Core recovery and sample accuracy has improved greatly in recent years and ranges from poor to good for *pack sack* type portable drilling, to good to excellent for large wire line rigs using carefully controlled drilling mud, swivel tube core barrels when drilling relatively large drill cores in good rock.

5. Large diameter core drilling for obtaining bulk samples for metallurgical testing. Core sizes are typically PQ [85.0 mm ($3\frac{1}{2}$ in.) diameter], or 152 mm (6 in.) diameter which requires core barrels fabricated for the project. Core recovery is usually excellent and sampling accuracy excellent. The heavy core is somewhat awkward to handle and costs are usually 50% higher than conventional core drilling, but the benefits far outweigh the added costs if this approach eliminates some underground headings and results in a better three-dimensional metallurgical picture of the ore body.

Sample preparation technique is often as important a problem as sampling and assaying accuracy. It should be planned and supervised by people with experience with the specific type of ore. Systematic and methodical checking of both sample preparation and assaying should be done using outside laboratories. A typical sample preparation procedure for a base metal development drilling project would be as follows:

NX size drill core is picked up daily at the drill rigs and hauled to a central core shed. Before splitting it is photographed on 35mm color film for later rock mechanics and structural interpretations. Core is then laid out on logging tables for geologic and geotechnical logging and testing. Rock Quality Designation (RQD) and core recovery measurements are made. Geologic logging and measurements such as point load testing are then done. Assay breaks are either on arbitrary lengths [2 or 4 m or (5 or 10 ft) are common sample

intervals] or breaks picked by the geologist on the basis of lithology or ore mineralogy. This decision will be predicated to some extent on the expected grade control and selective mining problems. The geologic log sheet and rock mechanics log should include data entry format to facilitate key punch entry and easy readability. Computerization of geologic data should not be done at the sacrifice of good graphic geologic logs from which easily understandable geologic sections can be directly plotted.

Core samples are split using a hand or hydraulically powered core splitter and half of the core is preserved in the box for future reference or subsequent resampling. The assay split is crushed to 4.8 mm (3/16 in.) then split through Jones Splitters to one-eighth of the heads sample with the 4.8 mm (3/16 in.) reject stored for possible metallurgical testing or reassaying. The split is recrushed to -2.0 mm (minus 10 mesh), split to one-half weight and then pulverized using plate or ring and puck type pulverizers. Two assay pulps are split from the resulting sample. One of these is assayed and the second filed for check assays or composite assay samples.

Assaying procedures are highly variable in base metal deposits depending on the combination of elements which are of interest, effects of oxidation, presence of refractory constituents, and presence of native gold, silver, or copper, etc. Because of the many variables it is usually best to carry out a test program before deciding on an assay procedure for a given type of rock and mineralization. Most base metal assaying is now done by the atomic absorption method, but in some situations chemical colorimetric analyses are preferable, and a large volume of X-ray fluorescence and nuclear activation assaying is now being done where high assay precision is outweighed by the advantage of low cost and speed. It is very important in exploration programs to systematically send out for check assaying a split of every tenth or twentieth sample and to periodically compare the assaying results using statistical methods.

Other types of laboratory work are usually justified in base metal exploration programs. If hydrothermal alteration or precise identification of specific host rocks is important to the program, then a representative group of petrographic thin sections should be made. If sulfide textures or solid solution problems are important polished sections should also be made. X-ray analyses are useful in some mineralogical determinations, particularly in clay minerals, and the electron microprobe is often useful in identifying associations between elements and host minerals. Spectrographic analyses of composite samples are used to insure that no potential byproduct or coproduct in the ore has been overlooked. Absolute age determinations are being increasingly used to identify favorable ore-related intrusions since in most districts all hydrothermal mineralization is related to one intrusive event. These laboratory techniques in some organizations can be done *in-house* but in most cases lower cost and more accurate results can be obtained by using commercial labs or consultants with experience in the specific problem.

Bulk sampling for the purpose of obtaining representative metallurgical samples for bench or pilot mill tests usually involves a joint project between the metallurgist and the exploration geologist. The samples must have the volume and fragment sizes required for the metallurgical test and they must be sufficiently representative of the mass of the ore body in grade, mineralogy, grindability, etc. to demonstrate any lateral or vertical variations in the character of the ore body. Typical variations which may be present are a vertical change downward from strong oxidation to fresh sulfides, or a vertical or lateral metal zonation from, for

example, a copper-molybdenum core outward to a copper-zinc margin of a porphyry copper ore body. A metallurgical test program typically progresses from bench testing of composite assay reject drill core samples to pilot testing involving hundreds or thousands of tons of ore from underground declines, drifts, and raises or from large diameter core holes.

The following example from the Dizon project of the Benguet Corp. illustrates both efficient use of bulk sampling and the effective choice of development drill hole spacing. The Dizon ore body was originally tested by Nippon Mining and Mitsubishi with 42 BX and NX diamond core holes drilled on a grid of approximately 200 m (656 ft). Core recovery was relatively poor and a significant fraction of the gold originally present in the oxide portion of the ore body was lost from the core samples recovered. The Nippon project was also completed when the price of gold was low and the gold content was less significant, but at the present gold price, the 1.0 gmt gold credit has more value than the 0.5% copper credit.

One of the most important decisions in planning a development drilling project is selection of grid drill spacing. In porphyry copper projects this spacing usually falls in the range of 76 m (250 ft) (Mission mine, AZ development drill spacing) to 183 m (600 ft) (Kalamazoo mine, AZ drill spacing). Typical hole spacings are 100 m or 400 ft. Factors which influence this are the uniformity of ore grade and mineralogy, degree of structural dislocation, and the expected viability of the ore body: a deposit which is clearly viable can be drilled on wider spacing than a marginal ore body. A statistical study by Benguet of the Dizon drilling indicated a change of less than 0.01% Cu between the 200 m (656 ft) grid holes and the final 100 m (328 ft) grid holes.

Most of the 15 infill holes drilled in the Benguet exploration project were large diameter core holes [PQ 85.0 mm (3 1/2 in.) core] which were laid out so as to complete a 100 m (328 ft) grid as shown on Fig. 1. Several holes also twinned previous Nippon holes to calibrate the accuracy of the previous sampling and assaying. Large diameter core samples were divided on 15 m (49 ft) bench intervals, and an individual bulk flotation bench test was completed for each bench interval in each drill hole through the entire thickness of the ore body. The result was a complete three-dimensional metallurgical picture of the ore body. In addition three adits were driven on two levels of the ore body from which a sufficient tonnage of ore was mined for pilot mill testing and development of a mill flow sheet. The large diameter core holes served three functions: calibrate the ore grade, fill in the drill grid to a 100 m (328 ft) spacing, and provide a representative set of bulk metallurgical samples.

Bulk samples from underground workings present a difficult sampling problem. A typical 18 t (20 st) muck sample must be reduced to a representative 4.5 kg (10 lb) assay sample. This normally requires construction of a sample mill. Channel and car samples may also be collected for comparison. An example of a well-designed sample mill is the Quintana Minerals mill installed during the evaluation of the 53.7 Mt 0.42% Cu, 0.012% Mo Copper Flat porphyry copper ore body at Hillsborough, New Mexico. (Dunn, 1981). The bulk metallurgical sample was derived from a 190 m (623 ft) minus 15° decline from which two drifts totaling 478 m (1568 ft) were driven into the ore body in a Y pattern. The sample mill was laid out as shown in Fig. 2.

GEOTECHNICAL STUDIES AND HYDROLOGY

Rock mechanics studies are done for essentially all new open pit base metal mines. The importance of this work is greater for deep pits and where wall rocks are relatively

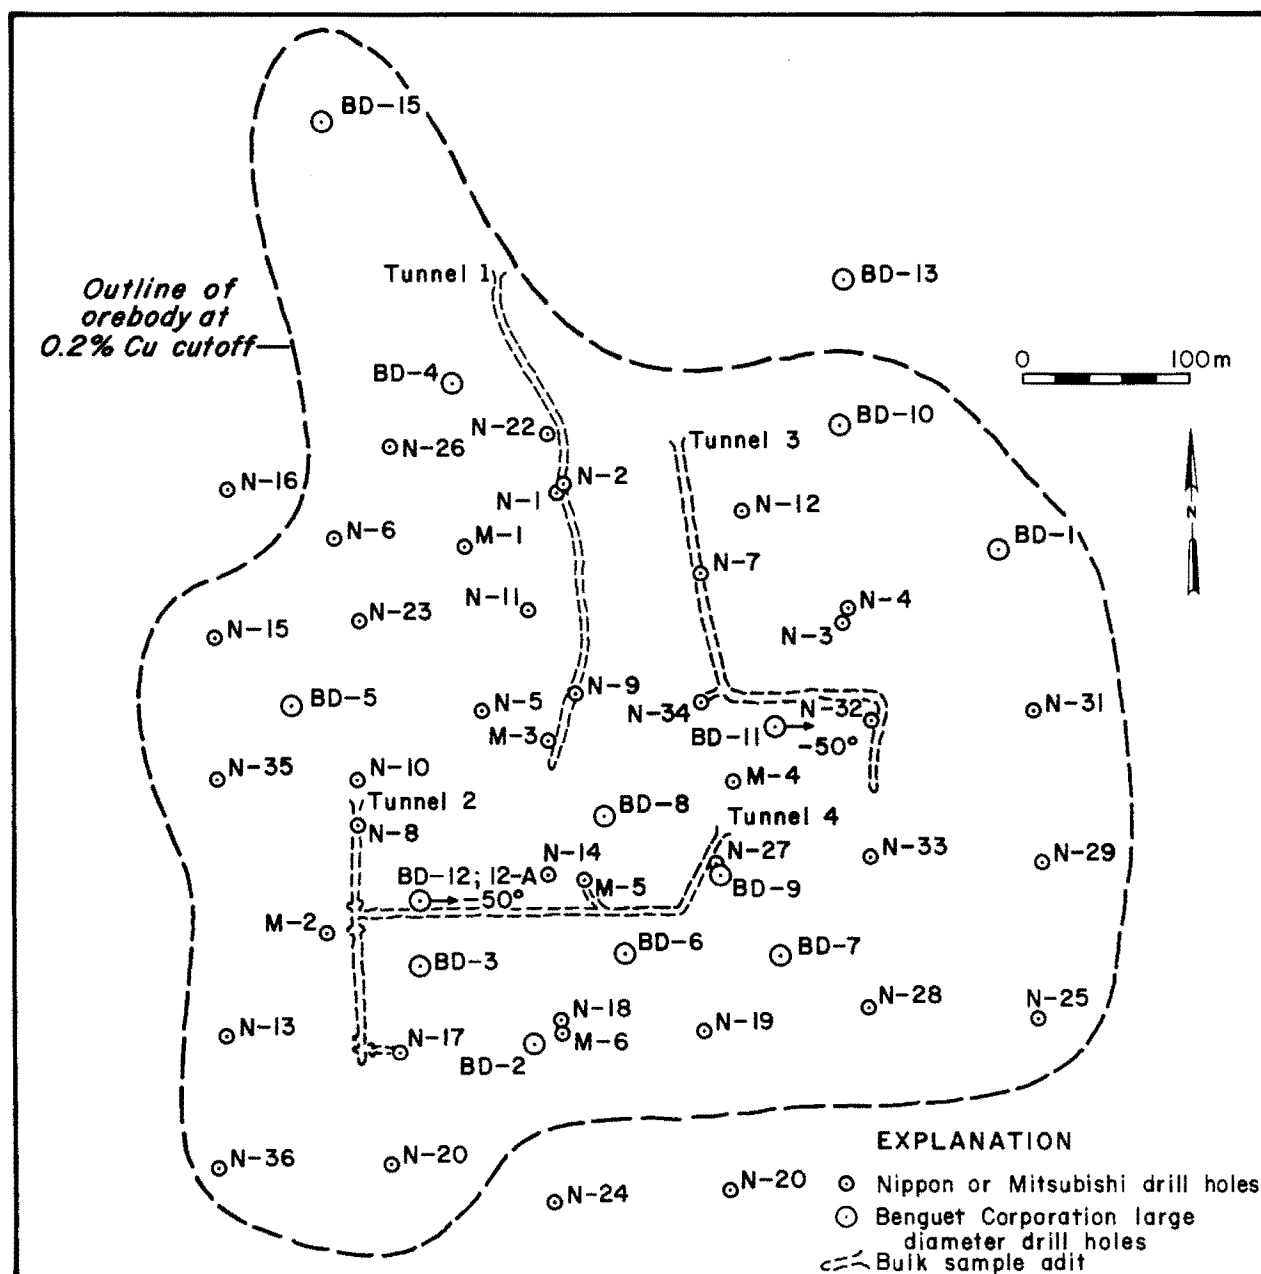

Fig. 1. Drill hole location map of Benguet Corp.'s Dizon copper ore body.

incompetent, but there are applications in all surface mining operations. RQD or other fracture density information should be collected during an exploration drilling project as soon as the possibility appears that the prospect might develop into a commercial ore body. Measurements usually made include point load testing, specific gravity, and sometimes compression testing.

These data are used to predict pit slopes, powder factors, fragment size, and water flow and give some information which can be integrated with metallurgical testing to determine overall grindability and power factors, etc.

Geostatistical analyses have been widely applied to mineral exploration in recent years, with the results ranging from good to poor. The best results have been obtained in mine planning studies in large homogeneous ore bodies lacking

structural dislocations; the poorest results have been obtained in studies intended to interpret the geology rather than the ore distribution in complex ore bodies. In general it is never safe to depend on a geostatistical ore reserve calculation during the exploration phase of a base metal project without carrying out a conventional ore reserve calculation based on polygons or sections and utilizing all available geologic maps and sections. Geostatistical techniques become increasingly useful as the overall shape and general grade distribution become clear and repetitive three-dimensional grade calculations are needed rather than geologic interpretations.

Water flows into the mine and a water source for the plant and camp are important problems which may be covered by the project geologist but which are usually given to a consulting groundwater geologist or hydrologist. If water

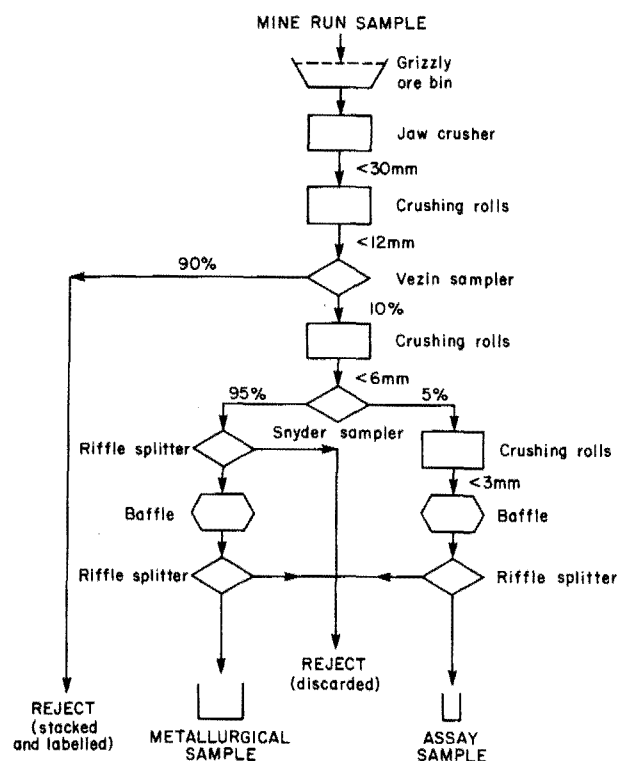

Fig. 2. Flowsheet showing preparation of underground samples.

problems are suspected, pump tests may be made on exploration drill holes, and water flow and static and drawdown water tables observed. However, since the average exploration drill hole is not well suited to hydrologic observations, except for measurement of static water table, groundwater information is usually collected from a well field constructed for that purpose. A recent paper by Montgomery and Harshbarger (1985) describes a very successful ground-water exploration project in the Andes range in Chile and Peru.

2.3 Precious Metals Exploration and Geology

BYRON S. HARDIE

INTRODUCTION

Exploration and geological techniques have different meanings for different geologists. The definition of *technique* in Webster's Collegiate Dictionary varies somewhat with time, but science, ability, expertness, music, and writing are key words; implied is study, logical analysis, hard work, and experience. Each geologist and nongeologist is as unique as his fingerprints; likewise are the ore bodies for which he searches and sometimes finds.

The politics and economics of the 1960s and 1970s have turned gold into a desired metal again. The western Cordillera within the conterminous US is an important source of many metals and is increasingly important as a gold province. The classic gold vein districts are largely mined underground, but the recently discovered and now important disseminated gold deposits are nearly one hundred percent mined by surface methods. This is a result of geologic environment, modern earthmoving methods, metal price, metal content, and the present inability to locate nonoutcropping deposits.

In the western US, the current focus for disseminated, bulk-minable gold is in the Great Basin and largely in Nevada. None of the occurrences identified to date has been lacking in outcropping, assayable gold mineralization. Such mineralization is essentially impossible to identify by panning or other gravity methods. Gravity concentration does show associated minerals containing lead, zinc, copper, mercury, and other metals and nonmetals often associated with the gold mineralization. Chemical or fire-assay analysis is essential to identify the gold. All such gold deposits found to date have been within or adjacent to mineralized areas of record.

Nevada, centrally located in the Great Basin, contains the largest number of reported disseminated gold deposits. The discovery of the Carlin gold mine north of the town of Carlin in north central Nevada gave increased impetus to precious metal exploration by those who anticipated increasing gold prices in the early 1960s. The three and one-half million ounce gold content in the Carlin ore body, as originally defined in 1965, was ideally suited to surface mining and easy extraction by proven cyanide metallurgy.

The Carlin gold discovery was the result of a search by experienced geologists for a specific deposit type in a specific environment. The successful effort initiated by top management of the forty-year-old Newmont Mining Corp. was guided by pre-WWII gold mining experience (Ramsey, 1973).

The Carlin discovery was equally the result of several decades of intense, sophisticated geological study of structure, sedimentation, and mineralization by the US Geological Survey (USGS) (Roberts, et al., 1958; Roberts, 1960; Hardie, 1966; and Radtke, 1981).

Increasing gold and silver prices stimulated discovery of additional deposits in somewhat different environments than those present at the Carlin deposit.

CARLIN-TYPE DISSEMINATED-REPLACEMENT GOLD DEPOSIT

Various terms have been used to describe surface minable gold deposits and gold-silver deposits that contain minerals and native gold-silver disseminated in a similar manner to copper minerals in a porphyry copper deposit. The gold-

silver and associated minerals are rarely detected by the unaided eye. The terms often used for this type gold and gold-silver deposit include: disseminated, disseminated-replacement, Carlin-type, micron, invisible, non-pannable, bulk-minable, and sometimes, porphyry-type.

The alteration of rocks occurring with Carlin-type gold and silver mineralization is seldom as spectacular as are the gossans occurring with outcropping copper deposits. The silica, clay, arsenic, antimony, mercury, pyrite, carbon, and carbonate alteration is often too subtle to recognize by casual visual inspection in outcrop, but often is recognized in new excavations that can be sampled in detail.

A brief description of the geologic and mineralogic setting of the Carlin-type disseminated-replacement gold deposit may explain some of the various descriptive terms used herein.

In 1971, the US Geological Survey modified earlier Nevada metal deposit classification by Ferguson (1929) to better accommodate the disseminated gold deposits of Getchell, Gold Acres, Carlin, and Cortez (Roberts et al., 1971). On the basis of form and host rock, gold deposits in north-central Nevada and southwestern Idaho were divided into three major classes: replacement deposits, disseminated deposits, and veins. The replacement deposits are divided into pyro-metamorphic deposits, base-metal replacement deposits, and peripheral gold deposits. Carlin-type disseminated gold deposits (1971 terminology) are treated separately as a distinct class, and are described as a special kind of replacement deposit in that large amounts of carbonate are replaced by silica, but they contain mineral assemblages which more closely resemble those of the low-temperature veins than those of the replacement deposits. Unoxidized ores in the Getchell and Carlin deposits are characterized by pyrite and realgar; in the Carlin deposit by cinnabar, stibnite, and a little galena and sphalerite; and in the Cortez deposit by only pyrite and gold. In 1971 the known, disseminated gold deposits were considered to be spatially related to the Roberts Mountain thrust fault, located below the fault in carbonate rocks where the thrust had been domed. Fractured permeable ground and precipitants such as carbonate or organic carbon were considered to be requirements at that time.

Radtke and Dickson (1974) later dropped the Roberts Mountain thrust fault as a characteristically associated feature but included as host rocks thin bedded carbonaceous, silty carbonate, fine-grained silicified rocks and jasperoids, zones of oxidized rocks above unoxidized rocks, and argillized rocks.

DISSEMINATED GOLD AND GOLD-SILVER DEPOSIT EXAMPLES

Examples of disseminated gold and gold-silver deposits in different geologic environments as currently defined by active explorationists are listed here.

Carlin-Type Disseminated-Replacement Gold Deposit

The following deposits are considered Carlin-type (Radtke and Dickson, 1974a, 1974b; Hausen and Kerr, 1967)

Bell (Jerritt Canyon), Elko Co., NV	(Producing mine)
Carlin, Eureka Co., NV	(Producing mine)

Blue Star, Eureka Co., NV	(Inactive mine)
Bootstrap, Eureka Co., NV	(Producing mine)
Cortez, Lander Co., NV	(Producing mine)
Gold Acres, Lander Co., NV	(Producing mine)
Gold Quarry, Eureka Co., NV	(Inactive mine)
Mercur (Getty), Tooele Co., UT	(Producing mine)
Northumberland, Nye Co., NV	(Producing mine)
Pinson (Ogee), Humboldt Co., NV	(Producing mine)
Prebble, Humboldt Co., NV	(Prospect)
Standard Pershing Co., NV	(Inactive mine)
Tallman (Duval), Cassia Co., ID	(Inactive mine)
Whitecap (Manhattan), Nye Co., NV	(Inactive mine)
Maggie Creek, Eureka Co., NV*	(Producing mine)
Rain, Elko Co., NV*	(Prospect)

*Added 1983, by Hardie.

Bulk Disseminated Gold Deposits in Volcanic Environment

This class deposit is described as occurring in a variety of geological environments spanning most of geologic time (Worthington, 1981).

Delamar (Silver City), ID	(One-third income from gold)
Gilt Edge, SD	(Inactive)
Golden Sunlight, MT	(Producing)
Haile Gold Mine, SC	(Developing mine)

Disseminated Silver Deposits

Described by Graybeal (1981) as having a silver to gold ratio of greater than 33:1, and containing four to ninety million tons. These deposits are considered from the standpoint of distribution of values rather than the physical location of specific minerals, and they are characterized by assay cutoff values. Tabular mineral concentrations are minor and less selective mining is normally required compared to vein and replacement deposits. Examples are:

Candelaria, NV*	(Inactive)
Commonwealth, AZ	(Inactive)
Creede, CO	(Inactive)
Delamar, ID*	(Producing)
Flathead, MT	(Inactive)
Hardshell, AZ*	(Inactive)
Hercules, ID	(Inactive)

Nevada Packard, NV	(Producing)
Rochester, NV	(Inactive)
Round Mountain, CO	(Inactive)
Santa Fe, NV	(Prospect)
Taylor, NV	(Producing)
Tombstone, AZ	(Producing)
Waterloo, CA	(Inactive)

*Watson (1977).

Bulk Tonnage, Low Grade Deposits

Described by Watson (1980) as a specific type that can sometimes be classed as a base metal deposit dependent on associated base metal prices. Examples listed earlier by Watson (1977) are included in the list above by Graybeal (1981). Other examples given by Watson (1977) are:

Hog Heaven, MT	(Inactive)
Langtry, CA	(Inactive)

Real de Angeles, Zacatecas, Mexico	(Producing)
Sam Goosley, BC	(Producing)

EXPLORATION

The objective of mining exploration is to find a new mine or identify an old one that can produce at a profit. This single function is the starting point required to extend the life of an active mining company. It matters not where or how the mine is found if it can produce a marketable metal that results in profit to both miner and consumer. The product can be any metal or nonmetal if compatible with corporate capability and consumer need.

Target-Identification

The listed gold and gold-silver deposits in preceding paragraphs are mineral occurrences that have either produced in the early part of this century or occur in active or formerly active mining districts. Not one represents an original discovery made more than a mile or two distant from known mineral or formerly producing mines—all outcropped and were partly eroded; not all are yet proven to be economic metal deposits. A few of these deposits are yet-to-produce and were partly talus-covered when discovered but showed visible surface alteration and small amounts (often less than 1 ppm) of detectable gold mineralization.

Only a half-dozen of the producing deposits and prospects listed would have been profitable in 1965 when the Carlin mine began production with the gold price fixed at \$35 per troy ounce. Some of the mines and prospects listed will not be economic if prices of gold and silver do not continue to rise. The profit margin on many will be slim or nonexistent unless management continues to increase operating efficiencies. Management includes the intelligent assessment of geological-mineralogic controls of mineralization and accurate evaluation of metal content before large capital sums are committed. These latter items are deceptively basic but are often given too little attention.

Some of the known and economic or potentially economic deposits may be replicated within one or two miles from the original discovery. The geologist must learn by observation and experience to recognize visible alteration and a permissible environment that accompanies the sought-after metal. Red, brown, and light-colored gossan and silicification often rises above talus cover. Bleaching resulting from clay alteration that results in a leprous, unnatural blemish on the hillside can be a subtle guide to mineralization. Alteration effects that are not visible but identifiable by chemical means can be guides to economic mineralization. Recognition of this described environment will require careful and detailed field work. Less than total effort by the prospector-geologist will miss outcropping targets.

All environmental details that have proven to be guides to precious metals mineralization often occur without metal or economic metallization. When metal is present, it does not occur uniformly distributed through the host rock even though it may be disseminated in occurrence; it is possible to sample in or adjacent to any of the listed gold or gold-silver occurrences and conclude that they are silicified and bleached but barren of economic metallization. Even if arsenic and mercury sulfides are glaringly visible as in some developed gold and gold-silver deposits, their presence is no guarantee of metallization if identified on an otherwise barren-appearing hillside.

The preceding will sound familiar to all exploration geologists who have looked for mineral deposits using all available *state-of-the-art* geologic guides. The haunting thought

is always present: "How do we find a gold-silver deposit that does not outcrop?" Success in finding outcropping disseminated gold deposits to date has been a function of some outcrop exposure and the ability to recognize the potential target.

To date geophysical methods have been of limited aid in the search for the disseminated gold and gold-silver deposit that does or does not outcrop. Copper deposits are relatively more responsive to geophysical probing, but they also are not always simple to detect.

The sophisticated chemical, x-ray, atomic and neutron analytical methods combined with space photography and sensing methods provide data on both the micro- and megascale (Ellett, 1981). The geologist has to work in between the extremes. Some geophysical technique application aids are helpful in the search for surface minable gold-silver deposits, but our instrumentation capabilities manage to stay ahead of our interpretive skills. The flood of numbers from computerized data must be properly handled to provide time required for field interpretation and application; most of today's deposits were found without today's technical backup aids. We must learn to convert our computerized numbers to recognizable three-dimensional concepts.

In the meantime, we continue with the methods that have become familiar and at least partially successful: face-to-face confrontation with rock, pick and sample sack, but leaning more on sophisticated analytical interpretation to collect raw samples with greater discrimination.

Investment Opportunity

The possibility of acquiring an identified mineral deposit or participating in its development and mining can contribute to the success of exploration. In a period of increasingly tight and expensive financing, exploration funds can often be more profitably applied by joint ventures involving two or more compatible partners. Such opportunities are often identified at the corporate level, but the exploration geologist should be able to recognize such potential as a result of daily exposure. The skills used in the discovery of new mineral deposits are needed in evaluating known mineral deposits.

Examples of mining companies, oil companies, utility companies, and other successful business organizations that have the financial capability to acquire developed and/or operating mines are recorded in the news releases and are well-documented in mining journals. Such acquisitions, if successful, are usually concluded following detailed examination of proven and/or potential ore reserves, mining, milling, refining, and marketing costs that will affect capital required and acceptable returns on investment; tax expense or credits are often critical factors in considering such acquisitions.

Examples of Successful Target Identification

In the past fifty years, mining, milling, and ore finding methods in the US have had variable success in meeting the increasing needs for many metals. The following examples illustrate the recent discovery approach used on some of the earlier listed gold and gold-silver deposits in which gold has been the predominant metal of interest:

Nevada Discoveries

Years 1930-1940

Getchell Mine, Humboldt Co., NV: Discovered by prospectors near old tungsten workings. Red and yellow arsenic in black carbonate accompanied gold in limestone.

Years 1940-1950

Gold Acres Mine, Lander Co., NV: Discovered by experienced mining company by examining a known producing gold district with turquoise prospects in carbonate sediments.

Bluestar and Bootstrap Mines, Eureka/Elko Counties, NV: Discovered by prospectors mining turquoise, barite, and antimony in a small placer gold district with known gold veins on dike contacts in sediments.

Years 1960-1970 [Gold decontrolled, 1968]

Carlin Gold Mine, Eureka Co., NV: Discovered in 1961 by experienced gold mining company geologists using a model patterned after mine districts at Manhattan, Getchell, and Gold Acres, all in Nevada. Outcrop sampling identified gold and antimony in the small Lynn mining district. Gold was found adjacent to the Roberts Mountain thrust fault mapped by the USGS in carbonate sediments.

Cortez Gold Mine, Lander Co., NV: Discovered by experienced mining company geologists exploring for silver and copper in an old silver-turquoise mining district. USGS geochemical sampling identified gold in silicified limestone adjacent to the Roberts Mountain thrust fault.

Golden Sunlight, Jefferson Co., MT: Discovered by mining company geologists examining old gold mine on veins that showed disseminated gold in intrusive rock.

Years 1970-1980

Pinson Gold Mine, Humboldt Co., NV: Discovered by experienced geologists with a consortium of mining companies examining an old gold mine near the Getchell Gold Mine in carbonate sediments.

Bell (Jerritt Canyon) Gold Mine, Elko Co., NV: Discovered by experienced geologist and mining company exploring an old antimony district. Gold in carbonaceous sediments adjacent to Roberts Mountain thrust fault.

Smoky Valley Mine, Round Mt., Nye Co., NV: Discovered by experienced mining company geologist examining old lode and placer mining district. Gold in volcanics.

Alligator Ridge Gold Mine, White Pine Co., NV: Discovered by experienced geologist-pro prospector for experienced mining company. Gold in silicified limestone.

Sterling Gold Mine, Nye Co., NV: Discovered by experienced geologists for mining consortium in old gold-fluorite district in carbonate sediments.

California Discovery

Years 1970-1980

McLaughlin Gold Mine, Napa Co., CA: Discovered by experienced geologist for gold mining company at old mercury mine in known geothermal area near hot springs in volcanics, serpentine and clastic sediments.

Utah Discovery

Years 1970-1980

Mercur Gold Mine, Tooele Co., UT: Discovered by experienced geologists for oil company mining subsidiary in siliceous, carbonaceous, carbonate sediments in an old gold producing district.

Plan for Discovery

Nearly all of the listed examples were recognized or discovered by trained geologists having available sophisticated geologic and mineralogic backup supplied by capable mining companies.

The improving capability to interpret geological, geophysical, structural, and geochemical data will lead to discovery of the more subtle outcropping deposits that now

elude easy detection, and eventually the nonoutcropping deposit. All of the known deposits are accompanied by a surrounding halo of identifiable if not easily recognizable alteration and anomalous indicator metals.

New deposits will continue to be found in areas known to contain gold and silver mineralization. Published literature gives some of the best leads to potential gold-producing areas. Examination of these areas will indicate potential exploration targets.

HYDROLOGIC MODEL

Ore deposition models are best constructed on the basis of mine openings and drill hole data developed as a result of commercial operations supplemented by detailed mineralogic studies of metallization, alteration, and fluid inclusions.

The hydrologic model for the Creede Mining District, Central San Juan mountains, Colorado (Wetlaufer et al. 1979), is viewed as a fossil geothermal system. The lower Miocene Ag-Pb-Zn-Cu-Au ore deposit has had extensive study (Steven and Eaton, 1975; Bethke et al., 1976; Barton et al., 1977; Bischoff et al., 1981). This deposit has many characteristics that are similar to those known for intermediate depths in active geothermal systems. The postulated hydrothermal system is seen as a nearly closed convection cell of deeply circulating saline fluids, depositing and leaching gangue and ore minerals. Alteration caps were probably caused by condensing of acid volatile compounds (H_2S and CO_2) that boiled off the hydrothermal solutions. The ore zone is thought to represent only the top of the system.

Isotopic studies have shown that recharge of active geothermal systems is dominantly supplied by meteoric (surface) waters. Many geothermal fields are located in volcanic regions and commonly are associated with silicic volcanic rocks thought to be characterized by shallow magma chambers. The Creede district is noted for middle-Tertiary volcanism that could easily furnish the energy needed to sustain a hydrothermal system.

The Carlin disseminated replacement gold deposit has been extensively studied by the US Geological Survey and others using drill hole and deep open pit exposures (Hausen and Kerr, 1967; Dickson et al., 1979; Radtke, 1981). The hydrothermal system has characteristics similar to those noted at Creede and at other deposits. The Carlin deposit is thought to have formed at shallow depths, about 1500 m (4921 ft) below surface. Hydrothermal fluids furnished by meteoric water heated by Tertiary volcanic energy are believed to have leached and deposited ore and gangue minerals from and within the host Paleozoic carbonate sediments. This model is more widely accepted when there is visible evidence of nearby intrusive activity.

More information from recently discovered deposits will undoubtedly modify current hydrologic concepts. Detailed studies of geothermal systems with and without presently economic amounts of metals have been led and guided by the worldwide background studies sponsored by the US Geological Survey and university research groups. These scientific contributions will continue to influence new economic metal discoveries.

Choosing a Target Area

A procedure often followed in choosing areas that may contain potential targets is outlined below. Choosing a place to dig or drill when the explorer is a prospector or employed by a large mining company should mean that there is no known available target area that has a better chance for

success in discovering the desired metal deposit (Broderick, 1948).

One suggested procedure:

1. Personal experience.
2. Published and open file reports by the US Geological Survey, US Bureau of Mines, US Bureau of Land Management.
3. State Geological Survey.
4. County records: assessor, county recorder.
5. Information data banks in state and federal agencies, universities, and public libraries.
6. Mining and geological society publications.
7. Consultants.

Geological Target Maps

A preliminary target search will often suggest several areas that should be given a first look in the field before committing to an initial sampling program.

All published maps covering the areas of interest should be acquired and prepared for field use. A map scale of 12,000:1- or 24,000:1-scale topographic map or recent aerial photographs make good initial geologic or reconnaissance maps. Maps of 2,400:1- or 6,000:1-scale will be required to show details of fracturing, mineralization, and bedding attitudes.

Major faulting, fracturing, and bedding attitudes are critical to control of mineralization and to eventual design of surface pits for mining. Characteristics of faulting and structurally disturbed areas should be modified and updated when drill testing provides information.

Water occurrence should be noted where observed in mapping and drilling. Water sampling is sometimes useful in locating mineralized structures as well as a possible supply for drilling and mining operations. Water occurrence can be a problem in drill sample collection and in pit design.

LAND STATUS

Location maps in the initial reconnaissance of potential target areas should include land classification designations to locate federal, state, or county restrictions on land use. Mining claim location and other private ownership information should be determined by field reconnaissance and record search of Bureau of Land Management and county assessor-recorder offices. A mineral survey of property boundaries is low-cost insurance against future loss.

SAMPLING

Sampling programs are designed to determine the metal content and the feasibility of economically recovering that metal from a volume of material being investigated. A quote from Griffiths (1962) is well worth emphasizing.

"Any scientific investigation is no better than its sampling plan; inadequate sampling cannot be subsequently offset by any procedure, experimental or statistical. The problem of sampling arises in the initial stages of an investigation when setting up the most efficient means of achieving the main objective of the experimental program, and it crops up again at various stages throughout the experiment in attaining required levels of precision of estimates from different measuring techniques. Because of its fundamental role in experimentation, the sampling pattern should be decided upon at the same time as the overall strategy of the program, i.e., at the beginning; generally in sedimentary petrography it is resolved as the experimenter becomes aware of it, a certainly inefficient and, possibly, disastrous practice."

Sampling is a major step in the discovery of a mineral deposit, and in the early exploration stage must receive close

supervision by professional geologists. Sampling a mineral deposit after it has been identified is a critical step. Poor sampling procedure is common and has been for the past few decades of observation by the author. Careless sampling might not be damaging if there are no mineralogic characteristics that reduce metal recovery and no shortage of metal reserve. Remembering Griffiths' advice, careful sampling must be insisted on for every deposit at the outset of exploration, development, and mining; otherwise, a marginal deposit may fail after consuming unnecessary expenditures of time and dollars before problems are identified.

Disseminated gold deposits are limited in optional metallurgical extractive treatment and are often further plagued by interfering sulfides, carbon precipitants, and siliceous encapsulation of gold and/or silver. When low prices and high costs coincide, survival may hinge on effective initial sampling practice. Management efficiencies at this late stage could be nullified by late recognition of poor sampling procedures.

Disseminated replacement gold deposits appear to represent the definition of randomness and demand a systematic grid sampling plan that can be uniformly expanded or otherwise systematically altered as data accumulates. Gold deposits that contain less than two parts per million gold (0.05 ounces gold per ton) are economic at a \$500 gold price and lower if metallurgical characteristics are favorable.

Biogeochemical sampling may be more effective in some areas than other surface sampling methods when near-surface conditions are unfavorable for otherwise representative sampling procedure. The fine-sized gold in disseminated gold deposits is often soluble in oxidizing conditions when organic acids and/or sulphur are present.

The following references are some that will serve as dependable guides when selecting a sampling program: Barnes, 1979; Curtin et al., 1974; Ferguson et al., 1977; Harris, 1981; McKinstry, 1948; Overstreet and Marsh, 1981; Peters, 1978; Rose, Hawkes, and Webb, 1979.

Concurrent with sampling for metal values, samples for alteration studies should be taken where indicated. Often the specific need for such samples is not indicated until metal anomalous areas are defined when assay results are available. Magnetic susceptibility of various rock units requires samples to determine the advisability of magnetic surveys.

Sample Map

A topographic map on 6,000:1- or 12,000:1-scale can be used to establish a sampling grid that will develop as surface sampling and geologic mapping progress. Metal anomalies, alteration samples, metallurgical samples and major structure and rock contacts should be represented. This map will serve to plan a drill test if indicated by initial studies. Larger-scale maps (1,200:1- or 2,400:1-scale) will usually be required for detailed sample plotting and geological mapping.

Sample Preparation and Analysis

Effective collection of representative samples of any rock mass can only result from a carefully planned sampling program. There is always a tendency to favor the easily-chipped rock outcrop either on the surface or underground.

The detailed planning of sample collecting requires close supervision of sample helpers to avoid non-representative sampling. Inspection of sample book entries by the project geologist should be routine to help identify incorrect procedures used in sample collecting; drillers' reports should receive similar attention. Description of individual samples

in a sample book will often aid early recognition of mineralized rock types by comparing assay results.

Before sampling is begun, competent assay companies must be contacted and evaluated. Accurate sample preparation and assaying procedures are not to be taken for granted. Many mining companies now prepare their samples through the assay pulp stage to assure proper protection against salting and inaccurate size reduction procedure (Shaw, 1978).

Assay procedures are not usually difficult, but good housekeeping in commercial and private laboratories is an essential practice not always observed. Considering the critical nature of samples taken at the surface or from drill core and cuttings, it is imperative that the exploration manager assures himself that the most effective procedures are being followed. The samples may have less than one ppm gold and silver, and a decision may be made to commit millions of dollars on drilling an ore body that contains less than two ppm gold and forty ppm silver.

Assurance that correct sampling procedure is in place must be followed by continual checks on assaying results by comparative assays using coded duplicate samples and different assay firms. All competent assayers continually run checks on their own work.

DRILL TESTING

The decision to drill a mineralized area is ideally made as a result of several weeks or months of preparation of metal anomaly, geologic, property, water supply, and possibly, geophysical maps. A drill grid map and cross-section maps should be prepared to allow the project geologist to keep currently appraised of interpretations based on the results of drill sampling and geological logging. Access roads and drill sites must be prepared. Forest Service, Bureau of Land Management and/or local authorities must usually be contacted well in advance of drill site preparation. Negotiations with drill contractors follows a determination of those who are acceptable as judged by past performance. Assayers and sample preparation facilities should have already been arranged to provide sufficient service on assay results to avoid costly delays in drilling progress or inefficient drill planning. Sample collecting help should be already trained, and sample storage for future reference must be adequate to allow safe storage and retrieval of valuable samples.

Drafting help and office geological help should be adequate to plot and review drilling and interpret results. Interpretation of geophysical surveys or re-surveys should be kept current.

Several hundreds of tons of drill samples will be handled, i.e., collecting, splitting to assay duplicate and metallurgical test samples. Rockboards are often made from cuttings or chips from core or rotary-percussion samples to aid in geologic and mineralogic interpretation.

Drilling a ten million ton ore body can easily require 76 200 m (250,000 ft) of drilling equivalent to 625 holes 122 m (400 ft) deep. This equates to \$2.5 million at ten dollars per 0.3 m (ft) for contract drilling. This type ore body will often require an equal number of holes outside the actual minable ore body and these are included in the numbers used in this example. The cost to the point of feasibility can quickly reach \$5 million or \$.50 per ton for a 10 million ton ore body.

The costs in dollars and manpower of a major drill program are of a magnitude to require constant review and frequent decision points as to whether or not a drill project should be continued. Such decisions can only be made with

confidence when a well-organized plan allows daily review of all data. Currency of data available to make intelligent interpretations is aided by computer programs, assuming that all basic data are accurate.

Example: Ten Million Ton Disseminated Gold Ore Body

A few numbers relating to a drill test of a 9 Mt (10 million ton) disseminated gold or gold-silver deposit with rotary and percussion drilling will illustrate the logistics involved.

Assumptions:

Ore body size: 9 Mt (10 million tons)

Grade: 2.8 g/0.9 t (0.10 oz. average/ton)

Number of drill holes: 625

Average hole depth: 122 m (400 ft) \times 124 mm (4 7/8 in.) diameter

Sample interval: 1.5 m (5 ft)

Sample weight per 1.5 m (five-ft) hole: 68 kg (150 lb)

Cost/foot drilling: \$10 (\$32.80/m)

Cost/sample assaying: \$10

The drilling assumed in this example would result in 76 200 m (250,000 ft) of drill footage at an average of 14 kg (30 lb) of sample per 0.3 m (1 ft) [about 2.3 kg/0.3 m (5 lb/ft) for 51-mm (2-in.) diameter drill core]. The 3.4 kt (3750 st) of cuttings [or 567 t (625 st) of 51-mm (2-in.) diameter core] is often split four times using a Jones splitter to obtain two 4- or 4.5-kg (9- or 10-lb) samples [for an assumed 1.5 m (5 ft) drill sample interval] to provide for assay, rockboard, mineralogical and metallurgical test purposes.

The costs of this program for drilling and assaying alone would be \$2.5 million for drilling and \$500,000 for assaying.

Data Handling

Drilling data from sample assays, alteration studies and geological-mineralogical logging accumulates rapidly when good drilling progress is made. The number of drills operating on a project must not exceed, but should, at least, match the capability of the staff to effectively study, record, and interpret information acquired in a timely manner. A continuing problem on most drill programs today is preparation and analysis of samples and the plotting and interpretation of results. The availability of drill sample data controls the effectiveness of the drill program, and allows timely decisions.

Drill Sample Collection

The use of rotary and percussion drills in testing the disseminated metal deposits has resulted in better sampling in most instances than with diamond drill equipment. The cost of such drilling is often less than one-half that of diamond drilling. Samples from rotary-percussion drilling are two to six times as large as with drillcore, and sample recoveries are often more complete. Weighing samples can detect losses or caving in the hole that would otherwise go undetected. Screen analyses on samples will indicate the presence of coarse gold and the distribution of values. Losses of fines in rotary-percussion drilling can result in upgrading or downgrading of metal content in samples.

Drill Plan and Cross-Section Maps

Base maps should be constructed before drilling begins. Results of geological mapping and surface sampling should be plotted on plans and sections before drilling begins. An often critical step is proper orientation of vertical sections to allow effective drill hole orientation and geological interpretation.

All drilling data should be plotted currently to aid interpretation of mineral trends, alteration, attitudes of fault and dike structures with depth, and correlation of these interpreted features with those mapped at the surface. Often, close examination of drill sections can change the drill sampling plans and geologic interpretations based on surface study; also, additional surface study is often indicated by drilling results. The three dimension drill picture will often modify earlier concepts that may indicate termination of further drilling or may indicate additional drilling and possibly additional property acquisition.

Surface geologic plans and vertical cross-sections are used to confirm mineral projection and to give early indication of trends of total metal content for ore reserve estimation. Early in the geological mapping and drilling process, estimates of mining costs based on ore and waste distribution can be tested by hand and expanded by computer program.

Continuing estimates of geological reserves based on currently available drill results support judgment decisions and recommendations to management that should be made periodically.

Metallurgical samples should be collected and tested as soon as practicable to give mineralogical-alteration information and metal recovery numbers. This information is often valuable in making early estimates of ore classification that will indicate the need for different metallurgical treatment.

Assay-metallurgical information should be used by the geologist in conjunction with logging of drill core or cuttings. This approach will indicate the practicability of visual identification of metallurgical ore types.

Drill hole information should be used to evaluate the results of geophysical surveys or the need to recommend such surveys.

ORE RESERVES

The project geologist and his staff should maintain a continuing evaluation of geologic ore reserves. These evaluations are usually for an order of magnitude estimate and are not equivalent to the more detailed estimates prepared for final feasibility studies.

Geologic Reserves

Geologic reserve estimates are often made by outlining the ore exposed on vertical drill hole sections. Grade cutoff numbers and pit slopes are based on experience with current practice and economic guidelines as modified by metal prices, and mining and milling costs determined by operating experience. Metallurgical data developed during drill testing affect cutoff grades that may vary with different areas in the deposit. The influence of geologic structure, rock type, and alteration distribution must be accurately depicted on the geologic ore reserve sections. These data are essential to the final minable reserve estimates and pit design developed in feasibility studies. The original geologic reserve estimate will give a useful estimate of waste tonnage required to be stripped and/or mined internally during ore extraction. Dilution of ore with below cutoff grade and waste material will be estimated based on geological characteristics deduced from study of surface and drill hole information.

The geological reserve estimates usually should begin while drilling continues to define ore limits and extensions. This estimate will incorporate metallurgical data acquired by testing drill cuttings and samples from surface shafts, winzes or adits when indicated. In some instances, large diameter 152 or 203 mm (6 or 8 in.) drill core is effectively used at lower cost and better representative samples than obtained from other underground openings. Resident geol-

ogists at this stage often replace the exploration team geologists to coordinate with engineers in developing pit design and mine plans. Such matters as water supply, waste dump and tailings disposal plans should be assigned to the mine operation staff. The exploration team should be looking for another deposit.

Useful references on ore reserve estimation include: Brooks and Bray (1968), Hart and Sprague (1968), Hazen (1968), Peters (1978).

2.4 Uranium Exploration and Geology

DAVID C. FITCH

Uranium exploration is generally regarded as a specialized endeavor. Although some of the methods used are similar to those for exploration for other metals, and for oil and gas, there are certain techniques and approaches unique to the search for uranium. Unlike other metals, uranium typically occurs together with its radioactive daughter nuclides, and its presence is easily detected by a scintillation counter. Over the past 25 years, much of the land surface of a number of developed countries has been thoroughly prospected by airborne and ground scintillation surveys. Several of these efforts resulted in early discoveries of shallow uranium deposits. As a consequence of such activities, the chances are becoming increasingly remote for discovering a previously unknown uranium deposit that outcrops, especially in heavily prospected areas such as the western United States.

Therefore, a major part of most current exploration programs is directed toward searching for concealed deposits that have no direct surface expression. Such programs are based strongly on geologic factors, including a working knowledge of the size, shape, and grade, and a concept of the origin of deposits sought. Geologic criteria are used to select a favorable host rock and favorable areas that merit drilling. Company objectives, land availability, geologic setting of an area, and a continuing evaluation of field and drill data based on ore guides influences the overall exploration program and balances the exploration effort among several targets. Most uranium deposits occur as small targets within large areas of potential host rocks—a needle-in-the-haystack proposition. It is one of the more difficult metals to find in economic concentrations.

To be successful, an exploration program must begin with management that accepts the high risks involved and has the perseverance to see a program through perhaps as many as a thousand or more drill holes until discovery, an adequate budget, and a team of discovery oriented geologists.

TYPES OF URANIUM DEPOSITS

Known uranium deposits occur in a variety of host rocks and geologic environments, but significant deposits are commonly localized in specific hosts and environments. There are numerous papers describing the classification of uranium deposits and their origin. See, for example, Moench and Schlee, 1967; and Nash, et al., 1981, with their extensive bibliographies.

The following types are among the most significant:

Sandstone-type Host

The ore consists of uranium-enriched humate that coats sand grains and impregnates the sandstone, imparting a dark color to the rock. Deposits are commonly irregular in shape, elongate, and form distinct trends. They may be tabular or form rolls that cross bedding. A number of deposits show strong evidence of syngenetic or nearly syngenetic deposition in the host sandstone.

Examples of deposits are Colorado Plateau types, including the Morrison formation deposits of New Mexico; the Salt Wash deposits of Colorado and Utah; and the Chinle deposits, Lisbon Valley, Monument Valley, and White Canyon, Utah and Arizona; the Wyoming Tertiary deposits, Wyoming Cretaceous deposits, Texas deposits.

See Anon., 1980, 1980a, and 1980b for good summaries.

Precambrian Metamorphic Host

The ore consists of pitchblende, coffinite, and urano-complexes in certain favorable host rocks, commonly either 1.8 or 1.6 billion years old. Deposits are commonly controlled by structures or fractures.

Examples of deposits are Rabbit Lake, Key Lake, and Cluff Lake, Saskatchewan, Canada; Nabarlek and Jabiluka, Northern Territory, Australia; Roxby Downs, South Australia; Midnight mine, Washington; and Schwartzwalder mine, Colorado.

See Anon., 1978.

Precambrian Conglomerate Host

The ore consists of uraninite with thucolite (organic matter) and other heavy minerals, possibly as placer concentrates. Examples of deposits are Elliot Lake, Canada and Witwatersrand, South Africa.

See Pretorius, 1981.

Igneous Intrusive Hosts

The ore consists of finely disseminated uranium minerals in felsic igneous rocks. Examples of deposits are Rossing, Southwest Africa and Ilimaussag, Greenland.

Other significant types of deposits are in uraniferous lignite, black shale, and carbonate hosts such as the Yeelirrie, Western Australia (calcrete), and the Todilto (limestone) deposits in New Mexico (Carlisle, et al., 1978; Rawson, 1980; Schilling, 1975; Swanson, 1961; and Vine, 1962).

See Nishimeri et al., 1977.

GEOLOGIC LITERATURE STUDIES AND MAP COMPILATION

Based on literature and map review, experience, and ideas generated, a decision is made to search for a certain type or types of deposits that leads to the selection of a specific host rock known or thought to contain the types of deposits sought. Then a regional area of interest is selected. A regional map is compiled from available sources showing the outcrop distribution and known extent of the host rock together with all known uranium deposits and occurrences within the region. Deposits and occurrences that occur in the target host are marked with a bold map symbol to be easily seen. If drilling depths can be estimated, areas within shallow, open-pit limits are stippled. The scale of mapping to be used depends on the size of a region. Initial maps are commonly prepared at several scales ranging from 1:500,000, 1:250,000, and 1:125,000. Base maps at these scales may be obtained from the US Geological Survey, state, province, or county sources. Geologic maps from which the target host may be traced are commonly available from federal or state sources.

Maps showing uranium occurrences for some regions are available from the US Department of Energy, the US Geological Survey, or the IAEA and federal governments in some foreign countries.

Extensive literature research is conducted during the initial map compilation in order to plot all known uranium occurrences in the region. In some cases, occurrences may be plotted from listings in federal or state publications. The US Department of Energy maintains public files of prelim-

inary reconnaissance reports, arranged by county, that describe occurrences examined. Airborne scintillation and geochemical data of much of the United States was generated by the Department of Energy's National Uranium Resource Evaluation Program conducted several years ago. Other sources of data for the location of uranium occurrences are geology journal publications, scout reports, oil well gamma-logs, and in some cases, water well sample records on file with state agencies.

As the map compilation proceeds, the search is continued for all available data on geologic descriptions of deposits and occurrences within the region and the geology of the host rock. A tabulation of the occurrences is prepared with a description of the geology sufficient to make a preliminary ranking of their favorability. Based on data generated at this stage, favorable areas are selected for field study.

GEOLOGIC FIELD STUDIES

Before and during field evaluation of a favorable area, an effort is made to examine the geology of operating mines and known deposits similar to the targets sought. The geologic characteristics of mineralization in the host rock, alteration, and the geometry of the ore bodies are given special attention. Each observation of ore is examined with the following questions in mind: How did the ore form? Why is it located here? What are the halo characteristics related to ore that are not present in barren ground? When developing a concept of a deposit's origin to apply to the discovery of new deposits, it is important to keep in mind the idea of multiple working hypotheses. It is also necessary to modify the hypothesis as new facts are accumulated. An example of the chronologic development of genetic theories for sandstone-type uranium deposits in the United States is tabulated by Finch (1967). One should strive to develop, as soon as possible, a concept of origin that is accurate. Discussions of ideas with geologists who have discovered ore deposits are very helpful.

Ore guides are then developed, based on the above studies. These vary among the types of deposits and may range from general to specific. Ore guides common to nearly all uranium deposits are:

1. The presence of a proven host rock.
2. Anomalous uranium mineralization (two times background may be significant in some hosts; 20 times background may be required for other hosts).
3. Position of area with respect to mineralized trends, if any.

Additionally, the habit of uranium deposits is such that they commonly tend to occur in clusters, are elongate, and tend to form distinct trends.

A familiarization with the geologic setting and the experience gained from the above work may be applied to evaluating favorability of the study area. Generally, field examination of a potential area is conducted in stages. The first stage is a brief reconnaissance of the most significant occurrences and outcrops in the area. A hand-held scintillometer (Bailey and Childers, 1977) is commonly used to estimate the grade and extent of mineralization around previously plotted occurrences as well as detecting new ones. These are immediately examined and plotted on work maps. Careful attention to anomalies as low as two times background is prudent. Altered areas in the host rock are plotted, as well as the boundaries of the host.

Airborne scintillation surveys (Bailey and Childers, 1977) are commonly made at this stage, which may detect outcropping deposits, if any, or the surface expression of deposits concealed beneath shallow cover. The geologist directs the

airborne work and generally flies as observer to insure the flight lines are as chosen. Flight patterns are selected to parallel and thoroughly cover outcrops of the potential host rock. Grid patterns are generally only used in areas where specific host rocks are unknown. Altitude above ground level should be as low as good safety practices permit, because radiation decreases with the inverse of the distance squared. Flight levels generally range from 15 to 76 m (50 to 250 ft) above the ground. Either an airplane or helicopter is chosen depending upon terrain. Hand-held or airborne scintillation equipment may be purchased or leased. Spectrometers that distinguish between uranium, thorium, or potassium radiation are commonly used, especially in areas of metamorphic or granitic host rocks which often contain thorium. Airborne equipment commonly provides for strip charts, digital print-outs, or computer tape storage of data.

It is good practice to calibrate a scintillation counter (Nininger, 1954) before and during use. Some are equipped with an internal calibration setting and an adjusting knob. Others use an external radioactive source and a calibration knob. It is also good practice to obtain hand samples of ore of known grade for a rough estimate of instrument response for various grades of mineralization. It is difficult to estimate grade in a large outcrop of mineralization due to a mass effect. For this purpose, face scanner attachments are available for several of the scintillation and geiger counters (Key et al., 1982).

Geochemical techniques have been used in a number of uranium exploration programs (Dall'Aglio, 1973; De Voto, 1978; Grimberty, 1972). These techniques include uranium analysis of sediments, stream sediments, stream water and ground water. Results of uranium anomalies in stream and ground waters are generally difficult to interpret. Much of the uranium in water may have been derived from disseminated sources that are uneconomic. Also, composition of the ground water typically determines the amount of uranium that may be held in solution.

Another technique is radon emanometry which consists of measuring radon gas concentration in soil gas generally on a grid pattern over potentially favorable areas. If used, this technique is usually applied to specific drill target areas rather than regional reconnaissance. One method (Miller and Ostle, 1973) uses a one-meter (3 ft) long steel tube driven into the ground. Soil gas is pumped from the tube into an alpha counter with a silver-activated zinc sulfide analyzer. The radioactivity of the sample may be measured in counts per second and the data plotted on a sample map. Background values for the area must be determined several times per day because barometric conditions will influence radon emanations. Another radon technique uses alpha-sensitive film that is placed inside a plastic cup in a shallow hole about 0.6 to 0.9 m (2 to 3 ft) deep (Fleischer et al., 1980). The cup is usually left in place for two to three weeks, then recovered and the film processed. Alpha tracks on the film are then counted. The alpha film method is available from a service company, which supplies the film and cups, processes the film, and furnishes results for a fee. A good summary of radon methods is given by Bailey and Childers (1977a).

FAVORABILITY MAPS

As the reconnaissance work progresses, all significant data is plotted on a regional map at a suitable scale. The data to be plotted includes, in order of importance: (1) grade of uranium mineralization and percent eU_3O_8 or radioactivity in multiples of background at all uranium occurrences, (2) map extent of the host rock or structure if applicable, and

(3) map extent of favorable areas based on alteration and mineralization. Only in this manner can a regional picture be obtained and any significant patterns recognized. Areas may be ranked on the map as favorable, semi-favorable, and unfavorable, or assigned a numerical favorability ranking. In some geologic environments, it is possible to assign a numerical rating to each of the ore guides developed, with the greatest weight to the most important guides, and derive a total number of each data point. From such data, it may be possible to contour a favorability map.

Because there is nearly always competition from other exploration groups, the field studies are generally completed as rapidly as possible in order to acquire lands and generate drill targets. One never has all the answers to an area before moving ahead. In most successful exploration programs, decisions are made with the best, although often incomplete, data available.

LAND ACQUISITION

Once a favorable area (or areas) is selected and it has been decided to move ahead, it is necessary to acquire exploration and mining rights, together with the right of access. In actual practice, a determination is often made prior to field studies that there is a reasonable expectation of acquiring lands in the area of interest under favorable economic terms. Uranium exploration generally requires large land holdings because it is not possible to predict the specific location of deposits before discovery. Land requirements range from a small program involving 26 to 52 km² (10 to 20 sq miles) to large programs containing 260 km² (100 sq miles) or more.

The cost of acquisition and annual holding costs are important factors that must balance within the overall exploration budget. Payments to the owner from future production as royalty or other interest is an important factor affecting the economics of any deposit subsequently mined.

Mineral ownership varies depending on the area. In the western US, for example, there are large areas of public domain upon which mining claims may be staked. There are a number of professional surveying firms that offer services of determining land status and properly staking and recording mining claims for a fee. In a number of cases, individuals or companies perform the work themselves. A summary of regulations governing claim staking may be obtained from the US Bureau of Land Management and the individual state geological survey or bureau of mines. The cost of staking and recording claims which average about 0.08 km² (20 acres) varies from a low of about \$30/claim to \$150/claim or more in rough, tree-covered country. A minimum of \$100/claim annual assessment work is required to hold the claims. Mining claims held by others may be leased under terms that are negotiated. Private lands may be acquired under terms of a mining lease negotiated with the owners. Terms of a mining lease generally provide for payment of a royalty from production, annual lease rentals or advanced minimum royalties, and in some cases annual work requirements. Production royalty is regarded as one of the most important items as it affects the production costs and can make or break a deposit. Uranium royalties are typically in the range of 1 to 5% of the gross value of ores mined. Annual rentals or minimum royalties, if any, may range from 50 cents to \$5 or more per acre.

Land acquisition in other countries depends on local laws and regulations. In some cases, exploration and mining concessions may be obtained, or joint ventures may be formed with government or private groups. A detailed discussion of land matters relating to uranium exploration and mining is

given in Chapter 2, Section 11, of this publication. An excellent review of US mining law and leasing procedures with examples of typical lease agreements is given by Bailey and Childers (1977, Chapters 4 and 5).

DRILLING PROGRAM

Once a favorable area is selected and the lands are acquired, a drilling program is formulated and undertaken. Drilling is commonly conducted in three stages.

1. During the first stage, holes are drilled on a wide spacing to delineate favorable ground and to obtain geologic information. Holes may be spaced from 800 to 1 600 m (one-half to one mile) apart for sandstone-hosted uranium targets. Initial spacing may be closer for a Precambrian metamorphic or vein host where a more specific target area has been mapped.

2. During the second stage, holes are drilled on a closer spacing in the more favorable areas based on results of the first stage for the purpose of intersecting uranium mineralization. Holes may be spaced 300 to 900 m (1000 to 3000 ft) apart for a sandstone target, or closer for a metamorphic or vein target. Some programs use a grid pattern for drilling in the first two stages. However, if the targets sought are randomly located, a random drill pattern is preferred.

3. During the third stage, holes are closely spaced in mineralized areas to intercept ore-grade uranium mineralization. Once a discovery is made, four equidistant holes are drilled to offset the discovery hole (Fig. 1), and the resulting ore holes are again offset (Fig. 2). The purpose of offset drilling is to obtain a group of adjacent ore holes that is as large as possible, bordered by a rim of non-ore holes (Fig. 3). Barren or slightly mineralized holes are not offset. This is regarded as the most efficient method of determining an ore body outline that cannot be predicted before drilling.

Spacing between offset holes and the discovery hole varies depending on drill depths and continuity of mineralization. For shallow, open-pit uranium deposits, an initial offset pattern of 45 m (150 ft) is commonly used. If ore is difficult to intercept at this spacing, the pattern is moved in to 23 m (75 ft) or 15 m (50 ft). Commonly, one drill will be placed on offsets and a second drill is moved to widely spaced locations to seek additional deposits.

Choice of drilling equipment is based on the type of rock being tested and the accessibility of the area. For sandstone-hosted deposits, a truck-mounted rotary rig capable of drilling 12 or 12.7 cm (4 3/4 or 5 in.) diameter holes with a tricone rock bit is commonly used (Fig. 4) (Bailey and Childers, 1977b). A 1500 series rig is well suited for shallow drill holes and is capable of drilling to depths greater than 300 m (1,000 ft). The drill should have a dual circulation system for drilling with compressed air, or water and mud. The upper part of a hole is drilled by air as far as possible and the remainder of a hole is drilled by water and mud. An efficient method that is becoming increasingly common is stiff-foam air drilling. New types of detergent are mixed with high volume air to lift cuttings from a wet drill hole. Compressed air or water is pumped through a swivel connection at the top of the drill string, down the drill string, and through openings in the drill bit. The air or mud lifts drill cuttings up the hole to the surface where samples are caught. A portable steel mud pit is commonly used for efficiency and to eliminate the need for excavating earthen mud pits. A water truck with a capacity for 5 680 to 11 350 L (1500 to 3000 gal) is used to haul drilling water to the location. If a drill hole is completed entirely by air, it is generally filled with water to obtain a complete geophysical log.

Fig. 2. Map showing drill sequence to delineate deposit.

Rotary drill samples are generally caught on 1.5 m (5 ft) intervals and placed on the ground in rows of 30 m (100 ft) (Fig. 5). A portion of each sample is placed in a sample bag and marked with the hole number and depth interval. Samples should be washed if collected from drilling mud. Considerable experience is required by the drillers to obtain representative samples.

In some areas, it may be decided to core (Bailey and Childers, 1977c), selected mineralized zones with a diamond core bit to obtain samples for stratigraphic information, chemical assay, or metallurgical testing. In most cases where core intervals are selected at shallow depths of less than

120 m (400 ft), it is economical to drill the hole by rotary methods to the core point, and then convert to a drilling mud suitable for coring. The tri-cone bit is then replaced with a core bit and core barrel, and coring performed through the mineralized zone and an additional 3 m (10 ft) for logging purposes. Choice of core diameter depends upon the volume of sample needed, and cost considerations as larger core is more expensive. Typically, NX sized core 4.45 cm (1.75 in.) diameter or NXWL 6.07 cm (2.39 in.) diameter is considered adequate.

Drill core is removed from the core barrel and placed in a wooden, V-shaped trough by the drillers. The core may be

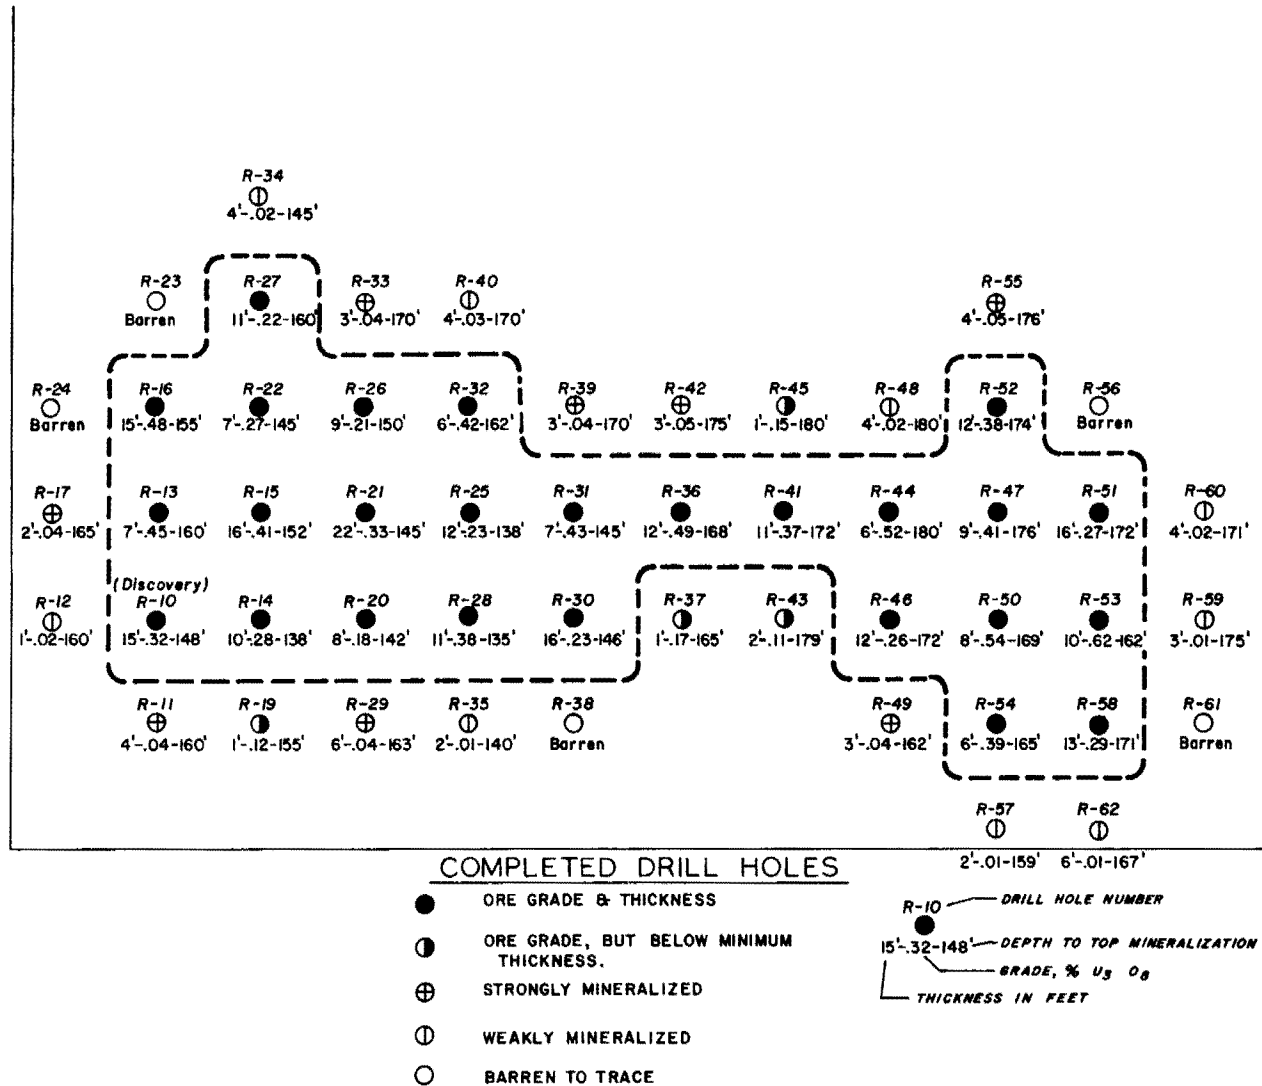

Fig. 3. Drill map of ore deposit.

removed by gently tapping the core barrel, or if there is abundant clay, a pressure hose from the mud pump may be connected to one end of the barrel and the core pumped out with gentle pressure from the pump. The core is placed in a core box as shown by Fig. 6.

The core is examined and scanned with a geiger counter to select sample intervals. The sample intervals should be selected with boundaries based on changes in mineralization or lithology. Thin intervals may be sampled [as small as 0.15 m (0.5 ft) thick]. In thick mineralized zones, a combination of contiguous samples is taken whereby individual samples are generally held to a maximum of 1.5 m (5 ft) thick. The core for the sample is split with a core splitter and one-half bagged for assay.

The lithology of either rotary or core samples is logged by a geologist in the field using a hand lense or binocular microscope. The data recorded (Fig. 7) include rock type, color, and grain size. Special attention is given to describing alteration features and the presence of carbonaceous matter or pyrite in the host rock. The presence and amounts of hematite and limonite are also given special attention. Notes

are generally made of accessory minerals, however, detailed notes are not usually made of the percentage of the common minerals. Core recovery is also entered on the lithologic log.

For drilling in metamorphic or igneous terrain (Anon., 1968) either core drilling or percussion drilling is commonly employed. For steeply dipping targets, the drill must be capable of drilling at an angle so as to intercept the target at as high an angle as practicable. Drill holes that intercept a target at less than a 20 degree angle may either glance off the target or deflect into the target resulting in an exaggerated thickness.

For coring, truck-mounted drills are commonly used (Bailey and Childers, 1977d). However, in areas of difficult access, skid-mounted drills are either moved in by winch and cable, or flown by helicopter. Helicopter-supported drill programs are generally expensive and occur in areas where future development costs may be expected to be high. Most core rigs now are equipped for wire line methods. A messenger is lowered by cable through the drill string to the inner core barrel at the bottom of the hole. Once a latch is completed, the cable retrieves the inner barrel with its core

Fig. 4. Typical drilling rig for uranium exploration.

to the surface. This method saves *tripping out* or removing all of the drill string to recover the lowermost core barrel.

Percussion drilling is also generally conducted with a truck-mounted drill, although portable units are available if required for rough terrain (Peters, 1978). A percussion or *hammer-tool* rig drills by compressed air fed to a pneumatic drill tool and bit at the bottom of the drill string. Hole diameter is commonly 15.2 cm (6 in.). Cuttings are carried to the surface and collected in a cyclone device that prevents escape of the fines. Samples are taken on a 1.5 m (5 ft) interval, split by a Jones splitter, and a manageable portion bagged and labeled for assay purposes. Lithology of the samples is logged in the field by a geologist. With a good driller, samples are generally representative to a depth of approximately 90 m (300 ft) or to the water table.

Percussion drilling is more rapid and is one-half to one-third the cost of core drilling. Percussion samples, however, are not as reliable as core. As a percussion hole reaches greater depth, there is usually slough and dilution by material above the zone being drilled.

Reverse circulation drilling is commonly used in exploration for other metals but less commonly for uranium exploration (Peters, 1978). The circulating fluid may be either air or water and mud. Drill pipe is double-walled and the fluid is pumped down the space between walls to the bit at the bottom of the hole. Cuttings are lifted up the center pipe to the surface. This method significantly reduces contamination in comparison to percussion or rotary drilling methods.

Drilling equipment with operators may be contracted from numerous drilling companies on a fixed price-per-foot basis or an hourly basis plus materials used. A less common practice is for an exploration company to own and operate its own drills. This practice nearly always requires that geologists spend a great deal of time directly supervising a drilling operation and obtaining parts and materials for the rig rather than devoting time to finding ore.

Drilling companies often have regional field offices in cities near exploration and mining activities. A listing of companies available in the area may be compiled from advertisements in the trade journals, listings in the appropriate telephone books, and phone calls to consulting geologic firms and geologists with other mining companies for recommendations. When the list is narrowed, it is advisable to call references for a recommendation of the drillers' abilities. Prices are often determined by inviting competitive bids from three or more contractors. Once a driller is selected, a drilling agreement spelling out prices and terms is prepared and signed by the driller and the mining company.

Fig. 5. Drill sample layout.

Fig. 8. Geophysical probe truck.

than claystones and shales. The spontaneous, or self-potential curve, indicates the natural potential differences in millivolts, between an electrode at the surface and an electrode in the probe in the drill hole fluid that is pulled up past different beds. This potential depends on a number of factors, but generally indicates the permeable zones, or sandstones, as a deflection left from the shale base line. Resistivity and SP logs are not as easy to interpret in igneous and metamorphic rocks. A summary of geophysical logging theory and practice is given in manuals prepared by Schlumberger (Anon., 1958) and Haun and LeRoy (1958). The gamma-ray log is used to interpret the amount of equivalent U_3O_8 in a zone by measuring the gamma radiation of radioactive uranium decay products. The scintillation probes in common use can delineate anomalous uranium mineralization down to approximately 7 or 15 parts per million eU_3O_8 . Ore values derived by gamma-log interpretation are relatively accurate in a number of known uranium districts. However, in most programs, a decision is made before drilling expenditures become large to determine if disequilibrium is a problem. Disequilibrium problems are discussed later.

GAMMA-LOG INTERPRETATION

The equivalent U_3O_8 content of a zone may be calculated manually from the gamma-log, or by computer methods which record the counts per second at one-half foot intervals and then calculate the equivalent U_3O_8 over mineralized intervals. The manual method most commonly used is described in detail by Dodd and Eschliman (1972), and Bailey and Childers (1977e). A typical calculation form based on this method is shown by Fig. 10. The method is based on a relationship $GT = KA$ where:

- G = grade in percent eU_3O_8
- T = ore thickness in feet
- K = instrument constant determined in test holes
- A = area of curve based on counts per second by 0.15 meter (0.5 ft) increments.

First, an upper and a lower bed boundary are determined to the nearest 0.3 m (1 ft), at a point about halfway between background and the peak of the gamma-ray curve (Fig. 9). A reading of the counts per second (CPS) is made at each of these boundaries and termed E_1 and E_2 . These are added and the total multiplied by 1.38 to provide for *tail effect* (shown by Fig. 10). Consecutive readings in CPS are then recorded for each 0.15 (0.5 ft) interval from the upper to the lower boundary. Each of these readings as well as the one for $E_1 + E_2 \times 1.38$ is corrected for instrument dead time

$$\text{by the formula } N = \frac{n}{1 - nt}$$

N = corrected counts per second

n = observed counts

t = unit dead time in seconds.

Most logging units now being used make this correction electronically and effectively have a zero dead time. The

counts per second are totalled and multiplied by a water factor, if any. The result is termed the *corrected area* [which is $CPS \times 0.15$ m (0.5 ft) increments]. The corrected area is then multiplied by the instrument K -factor. This result is divided by thickness to determine percent eU_3O_8 . A printout of the CPS values by 0.15 m (0.5 ft) intervals is also provided by most logging units (Fig. 11). In addition, the digital data may be obtained on computer tape and the tape processed by the logging company or a company-owned computer to provide thickness and grade of ore intercepts at various cutoff grades.

It is important that the probe be calibrated with a known source before logging each hole. This is usually printed at the bottom of the geophysical log (Fig. 9). When ore zones are being encountered, it is also important that the logging unit periodically probe a standard test hole with known thickness and grade in percent U_3O_8 . In the western US, several holes termed *test pits* are maintained by the Dept. of Energy for such purposes and to determine the instrument K -factor. It is good practice to request copies of test logs on a weekly or biweekly basis and file them within the sequence of ore holes drilled.

DISEQUILIBRIUM

Disequilibrium is a term for the disparity between uranium and its naturally occurring radioactive daughter products which are measured by the gamma log (Nininger, 1954a). Generally, checks are made for disequilibrium when drill-indicated reserves reach approximately 45 360 to 226 800 kg (100,000 to 500,000 lb) of contained U_3O_8 . In new areas, disequilibrium is checked after the first few ore holes. The procedure consists of coring a mineralized intercept and also probing the hole upon completion. The core is split along intervals bounded by changes in mineralization, based on scanning the core with a geiger counter. As a practice, sample intervals are held to less than 1.5 m (5 ft). Contiguous mineralized samples may later be calculated to a composite by a weighted averaging method. Split core samples are then bagged, labeled, and forwarded to an assay laboratory. Each sample is crushed and a portion split for pulverizing to prepare a pulp which is then assayed. Two separate assays are requested: a scaler-radiometric or closed-can radiometric assay, and a wet chemical assay (Grimald, 1956). The two assay methods are performed on exactly the same pulp. The ratio between the two assays is the disequilibrium factor, which is generally reported in the form chemical: radiometric, and should be so stated when discussing disequilibrium. This factor, which is of obvious economic importance, may be in favor of either the chemical or the radiometric assay. The chemical assays are then compared

Fig. 11. Gamma log printout of mineralized zone.

to the gamma log results for another check. However, in no case should this comparison be used for determining disequilibrium. The gamma-probe detects radioactivity through a 0.76 m (2.5 ft) diameter cylindrical area centered about the drill hole (Dodd and Eschliman, 1972). The core samples a cylindrical area of 4.45 cm (1.75 in.) diameter.

Choice of an assay laboratory is very important because there is a wide variation in quality. It is a good practice to seek recommendations from several of the larger and well-known consulting engineering and geology firms with a highly regarded reputation for experience in evaluating uranium deposits.

After an ore-bearing drill hole is logged, it is a good practice to drift survey the hole to provide an accurate location of ore zone intercepts (Linton, 1963). Although it is not common, a drill hole 122 m (400 ft) deep may deviate from collar to bottom as much as 9 or 15 m (30 or 50 ft). Hole deviation is principally caused by variation in rock type and driller ability.

The gamma-ray resistivity and SP probe is removed from the cable and a drift tool attached. The drift tool takes consecutive readings of azimuth and inclination at intervals of 15 or 30 m (50 or 100 ft). The results are tabulated in X,Y,Z coordinates at recorded depths and most logging companies provide a computer-generated map which plots the drift (Fig. 12).

Geophysical logging units with operator may be contracted from a number of available logging companies. The units are commonly truck-mounted, but portable units are available for helicopter or backpack transport to remote areas. Typical costs for a logging truck on a monthly basis are in the range of \$6,000 per month plus expenses and \$.10 per ft (0.3 m) for a gamma-ray, resistivity, and SP log. Neutron density, caliper, dry-wall resistivity, and temperature logs typically cost an additional \$.15 to \$.20 per ft (0.3 m) each. In areas near their district offices, logging trucks may be obtained on a call-out basis. Costs are charged for mileage, setup, and the footage logged.

GEOLOGY DATA HANDLING

Up-to-date drill hole maps and cross sections are most important for interpreting results and intelligently planning future drilling. As each drill hole is completed and logged, the holes should be inked onto a drill map together with the hole number, thickness and grade of each mineralized zone, and depth to top, or elevation at the top of mineralization. In a few cases, there have been exploration programs where something as basic as an updated drill hole map with values was never prepared, or where intercept values were not plotted for several weeks or months. Such a procedure rarely leads to success.

Drill hole map symbols should be chosen so that ore holes are boldest, and barren holes are weakest. An example of a typical drill hole map is shown by Fig. 3. A map scale of 2.5 cm = 3.2 km (1 in. = 2 miles) (1:125,000) is commonly used for a regional drill map and progressively smaller scales are used as needed to show detail. A typical progression consists of 1:24,000, 1:12,000, 1:4,800, 1:2,400, 1:600.

Regional and detailed cross sections are compiled as drilling progresses. These are especially important when drilling a deposit to determine correlation of ore zones from hole to hole, which is one of the most critical problems in evaluating the ore reserves and the economics of a uranium deposit. The cross sections should be oriented in a direction across the width, and along the length of the deposit. Cross sections may be prepared inexpensively and rapidly by photographically reducing the original geophysical logs from 1:120 (2.5 cm = 3 m) (1 in. = 10 ft) to 1:600 (2.5 cm = 15 m) (1 in. = 50 ft). Prints of the *mini-logs* may be taped to cross-section paper and the correlation made on the resulting print. As an alternative, the gamma ray and resistivity curves may be traced from the mini-logs onto mylar for a cross section. In addition to mineralization, the lithology, alteration, and structure are plotted on the cross sections. Detailed lithologic data is especially important for igneous and metamorphic hosts to determine if ore values are related to a specific rock

Fig. 12. Printout of drill hole survey.

type. Correlation of ore zones from hole to hole in uranium deposits often requires a considerable amount of judgment and experience. Multiple horizons, for example, are typical of sandstone uranium deposits (Fig. 13). As problems of correlation become evident, additional drill holes may be required to obtain the information needed to solve the problems.

Bench, or level, maps are plan maps prepared from the drill hole data to show the distribution of mineralization at various grade intervals on each consecutive bench or level. A typical bench map represents a 3 to 6 m (10 or 20 ft) vertical interval and is labeled by the basal elevation of that bench. Only the drill hole data within that 3 to 6 m (10 or 20 ft) interval is plotted on each drill hole. Ore reserves for each bench may then be determined by selecting a cutoff grade and using the general outline method or polygonal method as later described. Consecutive bench maps may then be superimposed, one above another, to determine continuity of ore from level to level.

Contour maps showing the product of grade in percent eU_3O_8 multiplied by thickness (GT or grade-thickness maps) are compiled for the total ore-bearing unit as well as individual subunits. Isopach maps of the host unit are also prepared. Favorability maps are compiled early in a drilling program and continually updated through the stage of drilling deposits. They are based mostly upon mineralization and

alteration intensity together with additional, less certain ore guides that have been developed. It is worth the considerable amount of effort and imagination required to determine mappable geologic features related to ore.

ORE RESERVE ESTIMATION

After a number of contiguous ore holes have been completed and the correlation of ore zones from hole to hole has been determined for a deposit, ore reserves are generally calculated. The subject of uranium ore reserve estimation is covered in detail in Chapter 3, Section 5.3. Several other papers which describe ore reserve estimation are Bailey and Childers, 1979; Blanchfield, 1980; Grundy and Meehan, 1963; and Harris, 1977.

A brief description of the methods follows. Typically, ore reserves are determined by either the general outline or the polygonal method. The first step is to assign a cutoff value based on thickness and grade of mineralization. The cutoff is determined by the economic factors of market price less the anticipated mining, milling, and capital costs. As one example, the average grade of uranium ore mined in Wyoming (almost entirely open pit) in 1982 was 0.067% U_3O_8 (Anon., 1983) and the corresponding cutoff grade would be less than the average.

For the general outline method, a map boundary is drawn around contiguous ore holes within a single ore horizon, to

Fig. 13. Idealized exploded block diagram showing typical relationship of prefault ore bodies in the Ambrosia Lake district, New Mexico, Granger, et al., (1961).

provide a boundary to the deposit, assuming that drill holes are spaced 15 to 46 m (50 to 150 ft) apart. The outside boundary is positioned one-half the distance between an ore and non-ore hole. The area within the boundary is determined by a planimeter, and the average thickness of ore is determined by an arithmetic average of ore thickness in all of the drill holes within the boundary. The average grade is calculated by a weighted average, based on the sum of grade times thickness for the zones in each of the drill holes, divided by the sum of ore thickness of all of the zones. The volume of ore (area \times average thickness) is converted to tons based on specific gravity of the ore.

The polygonal method yields similar results. First, polygons are drawn around each ore hole meeting cutoff. The polygons are constructed with boundaries that are typically one-half the distance from ore to non-ore holes. A tonnage and grade is calculated for each polygon. The tonnage is summed. An average grade is determined by a weighted average of tons times grade.

As mentioned previously, ore reserves may be calculated on each bench interval based on either the general outline or the polygonal method. A stripping ratio may then be determined based on tons of waste vs tons of ore for each level and for the total.

METALLURGICAL STUDIES

Samples for metallurgical studies are generally obtained in a deposit or several deposits when reserves appear sufficient to reasonably justify a commercial operation. In cases of deposits in a new area or new geologic environment, metallurgical samples may be required at an early stage of drilling.

The purpose of metallurgical studies, or more specifically, amenability tests, is to determine if the uranium and associated economic metals may be commercially extracted from the ores throughout the deposit, and to determine the recovery. Initially, samples are treated by established milling schemes at the laboratory scale. Various parameters are selected in processes such as crushing, grinding, types of reagents, reagent consumption, and precipitation, to determine the most economical extraction method resulting in an acceptable recovery. The volume of samples needed for initial testing depends on the variability of ore metallurgy within the deposit. Samples as small as 23 to 45 kg (50 or 100 lb) may be adequate for initial tests in some deposits.

Amenability tests may be performed under contract with one or more of the commercial metallurgical research companies that specialize in such work. Names, addresses, and recommendations of reliable metallurgical laboratories may be obtained by contacting mining companies currently operating successful uranium mills. In cases where the exploration company owns a mill and a metallurgical laboratory, they may prefer to conduct the work by their own staff. It is always advisable to obtain a check study by a second laboratory before completing feasibility studies.

Commonly, core hole samples within previously delineated ore reserves are taken for preliminary amenability tests. Because the mineralogy and amenability of ore may vary significantly throughout a deposit and from deposit to deposit, the selection of sample locations is very important. A preliminary decision of the number of core holes to be drilled and the location of these holes is based on the anticipated variation of ore types within the deposit or deposits. If amenability tests show a significant variation among the preliminary samples, additional coring may be required. In a case of a new deposit within a previously producing district with

a known history of commercial milling, the core holes may be as few as four or five per deposit. In cases of new deposits in unproven areas, numerous core holes may be required on a spacing as close as 61 or 152 m (200 to 500 ft). The number of holes and size of core depends also on the volume of samples required. Typically, NX sized core is chosen as a compromise between volume of sample needed and cost. Oversized cores ranging up to 15 or 20 cm (6 or 8 in.) in diameter are less commonly used because of excessive costs.

After the core is obtained, sample intervals are chosen based on changes in mineralization and lithology. The core is split or sawed in half and samples bagged for chemical assay. In cases where the entire core must be consumed for testing, the other half is bagged for assay along the same sample interval. After assay, the rejects and pulps are returned for preparing composite samples.

A decision of which samples to blend for a composite samples requires considerable attention to detail. The resulting composite should be representative and have a grade close to the average grade of the deposit. If there are two or more types of ore, samples from each type should be tested separately, followed by tests of the total composite of all types. Determination of anticipated grade of a composite sample may be calculated as a weighted average from the original assay data in the following manner:

$$\text{Average grade} = \frac{\text{sum of (weight} \times \text{grade) for each sample}}{\text{total weight of composite}}$$

Thickness may be used instead of weight if core recovery is near 100%.

After a composite is blended the resulting sample is assayed for a check against calculated grade. After the preliminary amenability tests, bulk samples are obtained from test pits for additional testing. If preliminary tests indicate the deposit has significant metallurgical problems, such as variable recovery and reagent consumption, the bulk samples are taken at an early stage. Bulk samples are often required for grinding tests although core samples may be used in some cases. If no significant problems are detected in the preliminary test, the decision to collect bulk samples is usually deferred, because of cost, until an overall economic feasibility study shows a deposit to be commercially viable.

2.5 Iron Ore Exploration and Geology

RALPH W. MARSDEN

IRON ORES: TYPES AND CLASSIFICATION

An iron ore deposit is a mineral body of sufficient size, iron content, and chemical composition with physical and economic characteristics that will allow it to be a source of iron either immediately or potentially. Economic viability is essential. No definite limits can be set on the size, grade, or mineral composition as there is a considerable permissible range in the physical and chemical parameters for a commercially minable iron ore deposit. Geographic location, other competitive iron ore sources, the size and location of the market, minability, grade and/or concentratability, are critical in defining the economic viability of a particular iron-bearing deposit.

Iron forms an estimated 5% of the earth's crust; it is a common constituent in hundreds of minerals and rocks, and in small amounts has an almost universal distribution. Iron in ore commonly occurs as an oxide in the minerals hematite (Fe_2O_3), magnetite (Fe_3O_4), or goethite ($\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$), and less often as maghemite (Fe_2O_3) and lepidocrocite ($\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$). Ilmenite (FeTiO_3) may occur in some ores up to the allowable limits for titanium in an iron ore. When of sufficient size and grade, as in the Michipicoten district, Ontario, Canada, siderite (FeCO_3) may be mined as iron ore. Iron sulfides such as pyrite (FeS_2), marcasite (FeS_2), or pyrrhotite (Fe_{1-x}S) are sources of small amounts of byproduct iron ore after removal of base metals and sulfur, or they may be the primary source of iron oxide gossans in the outcrop area of sulfide deposits. Iron silicate minerals commonly contain in excess of 25% silica so are not generally considered iron ore minerals, although they may be constituent minerals in some iron ores such as in magnetite taconites and in the Minette ores of France. Iron-bearing silicate minerals are frequently the primary source of iron present in secondary oxides produced by weathering of iron-rich rocks that form residual type iron ores.

Iron ores occur in a variety of geological environments in deposits with widely differing shapes, sizes, origins, and with substantially different ore characteristics. The diverse nature of the geology of iron ores must be recognized in exploration, evaluation, and in the investigative methods used in their study so the best possible discovery and developmental system is followed. There is, however, a general similarity of geology, problems, and occurrence of iron ores within each ore type that allows a reasonable basis for exploration, evaluation, and development planning.

The classification of iron ores shown in Table 1, which is based on a combination of geological and commercial factors, separates the iron deposits into groups having similar relationships and characteristics. This grouping places emphasis on geological and process factors. A general description of each ore class follows that summarizes characteristics important in the exploration, development, production, and evaluation of these ores.

Sedimentary and Metasedimentary Deposits

Precambrian Cherty Iron-Formation Deposits: The largest and most widespread iron ore deposits in the world are associated with Precambrian cherty iron-formations. These formations include a family of layered silica-rich and iron-

rich sedimentary and metasedimentary rocks predominantly composed of chert or fine- to medium- to coarse-grained quartz and iron minerals as oxides, carbonates, or silicates. The origin and occurrence of cherty iron-formations is discussed in an extensive literature. Commercial deposits of world significance occur in iron-formations as direct shipping, merchantable ores, concentrating grade ores, and as concentrating grade iron-formation ores. These sedimentary or metasedimentary iron-bearing rocks have a common occurrence in Precambrian terranes in rocks of Archean and Proterozoic age older than 1.8 b.y., with some jaspilite type deposits found in rocks with ages as young as Late Precambrian/Cambrian. In Archean rocks, the cherty iron-formations are associated with volcanic, volcanogenic, and sedimentary belts as deposits from a few meters long and centimeters thick to bodies 100 m (328 ft) or more thick and several kilometers long. There is a distinct tendency for Archean deposits to be lenticular. In contrast, the iron-formations in the Proterozoic often have an extensive occurrence within rocks deposited in sedimentary basins as stratigraphic formations from 50 m (164 ft) to over 700 m (2297 ft) in thickness and several hundreds of kilometers long. Proterozoic iron formations are commonly associated with clastic, or chemical sedimentary, or metasedimentary rocks and may or may not have volcanic rocks associated with them.

Cherty iron-formations are composed dominantly of iron minerals and silica that together comprise over 90% of the rock. These rocks are banded and layered with alternating iron-rich and silica-rich layers, ranging from 1 mm (0.04 in.) to 10 cm (4 in.) or more in thickness. The iron content ranges from about 15 to 50%. The commonly accepted definition of cherty iron-formation requires a minimum 15% iron content. The original iron and silica-rich sediment was deposited in a variety of sedimentary environments ranging from very quiet, undisturbed conditions to areas with considerable wave and current action. Deposition of most iron-formations appears to have been in relatively shallow water. The Dales

Gorge member of the Brockman formation in Western Australia has a very fine, microlayering undisturbed over extensive areas indicating very quiet conditions of deposition. As a contrast, some stratigraphic zones in the Biwabik formation, Mesabi Range, Minnesota have a granular texture, are lenticular, and wavy bedded with pebbly to conglomeratic, fragmental, and cross-bedded layers. Locally iron-formations are intimately interstratified with volcanic rocks, or volcanogenic sediments, or fine to coarse clastic sediments and in some rather restricted, usually local areas, contain thin interbedded calcareous carbonate sediments. Knowledge of the potential variability of cherty iron-formation depositional environments is important in the exploration, development, production, and evaluation of these deposits.

All iron-formations have been changed from the original sediments by diagenesis and in most areas by metamorphism. There is a continuing debate on the nature of the primary minerals, the source of the iron and silica, and the conditions of deposition. The characteristics of the original sediment, its mineralogy, bedding features, and the degree of segregation of the iron and silica into laminae or layers appear to have had a considerable influence on the present mineralogy and the distribution of iron and silica.

The post-depositional history including both deformation and metamorphism introduces important variables that influence the potential economic value and commercial viability of cherty iron-formation deposits. The importance of structure is evident as the complexity of the rock structure may determine the tonnage available and minability of a particular deposit. A high-quality, concentratable iron formation 30 m (100 ft) in thickness with a relatively flat dip and exposed over a sizeable area may be economically valuable, whereas iron-formation of the same quality dipping steeply even with a strike length of several kilometers would have little if any value as an iron ore resource.

The metamorphic history of iron-formations also may be of major importance in determining the potential value of a cherty iron-formation as a source of iron ore. During metamorphism the mineralogy, texture, and grain size of the rock can be markedly changed so as to greatly enhance or decrease its possible commercial value. Commercial cherty iron-formation ores are composed of iron oxides with associated chert or quartz and iron minerals whereas many of the primary iron-formations as sediments may have been largely composed of iron carbonate or iron silicate minerals with a very fine grain size and an intimate mingling or interlayering of fine-grained cherty quartz. Through metamorphism, the primary carbonate and silicate may be changed to magnetite, quartz, and iron silicates and the grain size, including the resulting oxide minerals, increased to sizes that permit easy liberation of the iron minerals by grinding, thus changing a valueless rock into a potential ore. Iron formations are found in many metamorphic stages from the lower greenschist through the granulite facies with lithologies that range from carbonate-silicate-chert rock, to magnetite-rich cherty rock with small amounts of associated carbonates and iron silicate minerals, to largely magnetite-quartz rock, to magnetite-hematite quartz rock with small amounts of iron silicate, and to hematite-quartz rock. There is a wide range of metamorphic iron-formation types which are associated with a variety of country rocks. Microscopic studies of the iron-formation are particularly important in determining the mineralogy and the intermineral, textural relationships. This information is particularly needed for an evaluation of concentrating grades of cherty iron-formation deposits. These studies should use both thin and polished

sections and include geologists concerned with the field as well as with laboratory aspects of the work.

Cherty iron-formation ores include deposits of Precambrian iron-formations that can be mined and concentrated to yield an ore grade product. These concentrating grade iron-formation ores are of growing importance as they are mined and processed on a large scale in the United States, Canada, USSR, Sweden, Norway, Tasmania, and China. The essential feature of a commercial quality, concentrating grade, cherty iron-formation ore is the occurrence of iron oxide minerals that after grinding will yield enough high-grade concentrate to permit an economically viable operation. There are several lithologic types of iron-formation currently being mined and concentrated in commercial plants.

These iron-formation types may be conveniently grouped as magnetite taconite ores, jaspilite ores, or itabirite ores. They are being concentrated by three different concentration systems, so the ores are grouped on the basis of iron-formation lithology and the applicable concentration system. Each ore type will be described; factors important to their study, occurrence, evaluation, and processing discussed; and viable approaches suggested for their exploration, development, and evaluation.

Magnetite Taconite Ore—Magnetite taconite or taconite ore is a term applied to a concentrating grade of iron-formation that can be processed to yield a high-grade shipping product by magnetic separation methods after fine grinding. Magnetite taconite is the preferred term because the term *taconite* on the Mesabi Range of Minnesota, where the term originated, includes all types of iron-formation regardless of mineralogy or the possibility of concentration. Some ores may require upgrading by fine screening or flotation after magnetic concentration, but the main treatment method is by a magnetic system. The chief ore mineral is magnetite with most other iron and gangue minerals rejected into tailings.

Magnetite taconite ores are a banded, layered sedimentary or metasedimentary rock commonly composed of magnetite and chert or fine- to medium-grained quartz with varying amounts of iron silicate minerals, iron-bearing carbonates, or other iron oxides. These ores include a considerable range of iron-formation lithologies in which the principal iron mineral is magnetite. The range in mineral content of the magnetite taconite ores on the Mesabi Range is determined by the metamorphic rank of the iron-formation. The Biwabik iron-formation metamorphic rank ranges from the greenschist facies in the western and central part of the area to amphibole and to pyroxene facies in the eastern range area. The greenschist facies magnetite taconite is composed of magnetite, cherty and fine-grained quartz with varying amounts of greenalite, minnesotaite, stilpnomelane, siderite, ankerite, and minor chlorite and chamosite. The amphibole facies taconite ore is composed of magnetite, fine-grained quartz with varying amounts of cummingtonite-grunerite, hornblende, ankerite, and calcite. The pyroxene facies magnetite taconite ore is composed of magnetite, medium-grained [0.1 to 3.0 mm (0.004 to 0.12 in.)] quartz with varying amounts of hedenbergite, ferrohypersthene, cummingtonite-grunerite, hornblende, and fayalite with lesser amounts of calcite, almandine, and andradite garnet. There is a gradational relationship between the metamorphic facies. A complex interwoven series of lithologic zones of magnetite taconite ore types are found in the transition areas that may be 1 or 2 km (0.6 to 1.2 miles) or more in extent.

Even though the magnetite taconite ores on the Mesabi

Range bridge a considerable range of lithologic types they do not include all possible mineral phases of these ores. For example, a green biotite is common in magnetite taconite in the Kursk area, Russia, and the magnetite taconite ore at the Empire mine, Michigan, which is very fine grained, contains magnetite, hematite, quartz, siderite, ankerite, calcite, chamosite, riebeckite, ripidolite, stilpnomelane, and minnesotaite.

Common features observed in magnetite taconites that are important characteristics of these deposits include the following.

1. Most deposits occur as tabular bodies ranging from a thousand meters to tens of kilometers in length and tens or hundreds of meters in thickness. In areas of complex folding individual deposits may have various shapes and not be tabular.

2. All deposits are magnetic and may be investigated by magnetic methods, but the interpretation of the magnetic information is sometimes difficult because of remnant magnetization.

3. Under certain geological situations gravity methods may be used to give valuable information regarding the potential size and occurrence of the magnetite taconite deposit.

4. Weathering of a magnetite taconite body results in the oxidation of magnetite to hematite and sometimes to goethite. The zone of oxidation may extend to depths of over 100 m (328 ft) in certain areas. Oxidation may be an important factor to consider during the study of an ore body. Since the weathered zone commonly has an irregular pattern both horizontally and vertically, a careful evaluation of the surficial zone of a magnetite taconite deposit may be necessary to determine the character and quantities of the oxidized material and of the mixed magnetite-hematite-goethite zone material. Studies of the zone of oxidation usually require drilling, although test pits, shafts, adits, and tunnels may be used. These studies must be associated with a program of careful sampling and laboratory testing.

Exploration for magnetite taconite deposits is often started with an airborne magnetic survey using a 400 m (0.25 mile) line spacing and low terrain clearance. The magnetic survey may be preceded by geological mapping, but if the magnetic survey data are already available, the mapping is commonly more effective. Geological mapping is usually accompanied by a ground magnetic survey of potentially favorable areas to give accurate magnetic control for use in selecting drill hole locations. Remnant magnetization is common in Precambrian iron-formations, which often limits the evaluation of the magnetic survey results to physical perimeters of the magnetite taconite occurrence such as location, extent, and structure of the deposit. The magnetic surveys can give information needed to design a core drilling program that will sample the deposits, determine its detailed geology, grade, concentratability and minability, and permit an economic evaluation of the deposit.

Jaspilite Ore—Jaspilite ore includes cherty iron-formations that are composed of alternating fine to medium-fine grained, hematite-rich layers and cherty to fine-grained, jaspery quartz layers with minor associated magnetite and other iron minerals. These ores are commonly red to red-brown in color with steel grey hematite layering. They occur as sedimentary or metasedimentary formations associated with clastic sedimentary, and/or volcanic or volcanogenic sedimentary rocks. Jaspilite iron-formations have a range in geologic age from Archean to Late Precambrian/Cambrian.

Jaspilite ores, also termed Michigan Jasper ores, were first produced on a commercial basis at the Humboldt mine

in 1954, and in 1956 at the Republic mine, Marquette Range, Michigan. Concentration is by froth flotation after fine grinding. The commercial Jaspilite ores in Michigan are crystalline with the hematite liberated from processing at about 0.21 mm (65 mesh) for some ore. The fine-grained ores are not being commercially concentrated but some deposits have been explored and much research on their beneficiation done.

Exploration methods that may be applied to jaspilite ores include geological mapping, airborne and ground magnetic surveys, and gravity surveys. Jaspilite iron-formations may contain sufficient magnetite to give a recognizable magnetic signature that will show the general size, shape, and extent of the deposit. Core drilling is the principal followup method to determine the nature of the deposit and to obtain samples for analysis and for laboratory concentration tests.

Itabirite Ores—Itabirite ores include commercial deposits of recrystallized, cherty iron-formation commonly composed of granular quartz, crystalline hematite, and martite with variable amounts of magnetite. The iron oxide-rich layers are interlayered with fine-to-medium and to coarse-grained quartz with more or less associated iron silicate minerals. The grain size varies from a fraction of a millimeter to several millimeters. These rocks characteristically are granular rocks and often are termed *quartzites* because of their texture. Their most common geological environment is with granulite facies rocks which often include granitic gneisses.

Itabirite ores are mined on a large scale in the Quebec-Labrador region of Canada at Fire Lake, Mt. Wright, Wabush Lake, and Labrador City. The first deposit mined in Quebec, at Jeannine Lake, has been exhausted. Itabirite ores range in composition from crystalline hematite and coarsely crystalline quartz with very minor amounts of iron silicate, to ores containing both magnetite and hematite interlayered with granular quartz with more or less associated iron silicate as amphibole or pyroxene, and minor calcite. There are extensive deposits of itabirite type ores in the Quebec-Labrador region of Canada, in Brazil, and in Venezuela. Similar deposits occur in Liberia and Sierra Leone, in West Africa, and possibly in other parts of this region north into Mauritania and south into Angola. Important characteristics of these ores are their simple mineralogy, moderate to coarse grain size, ease of liberation, and the simplicity of concentration.

Itabirite ores are mainly concentrated to yield a high-grade product by gravity methods followed by magnetic or electrical methods. In Quebec, the Fire Lake and Mt. Wright ores are concentrated by using spirals, and at Wabush by gravity methods followed by magnetic or high intensity electrical methods.

Itabirite deposits are typically tabular, occurring as stratigraphic formations associated with high-grade metamorphic or gneiss terranes. Even though deposits may contain only minor amounts of magnetite, magnetic survey methods can commonly be successfully used to supplement and assist geological mapping to show the location, extent, and the general shape and size of potential ore areas. In the Quebec-Labrador area magnetic anomaly areas with relatively low magnetic readings were associated with important hematite-quartz deposits such as at Jeannine Lake, Fire Lake, and Mt. Wright. In this region there are sufficient outcrops to permit a reasonable determination of the cause of magnetic anomalies. Airborne magnetic surveys may be used as a primary exploration method with followup ground surveys in areas of special interest. Followup ground magnetic surveys were helpful in showing the limits of the potential ore areas. Drilling is required to give positive knowledge of the

extent of ore occurrence, the grade and concentratability of the iron-formation materials. Deposits with a relatively high magnetite content generally respond to magnetic surveys in ways that are similar to the response of magnetite taconite deposits.

Cherty iron-formation ores commonly occur as tabular, stratigraphic units within a sedimentary, bedded, iron-formation. In some cases the entire formation may be iron ore, but in other cases only certain stratigraphic units will have the necessary grade, mineral content, and liberation characteristics to be an iron ore. Since these ores were deposited as a sediment, they can commonly be studied by geological methods applicable to other bedded formations, including sedimentologic, stratigraphic, and structural methods assisted by geophysical surveys. Geological mapping appropriate to bedded deposits should receive important emphasis, particularly in early stages of an investigation. Airborne and ground magnetic surveys are also commonly made early in an exploration program. Magnetic methods are used as an almost universal method often as an early systems approach. With the high quality and sensitivity of modern airborne magnetic surveys, they may be expected to give valuable information regarding almost any type iron deposit. Surveys that give completely negative results are extremely rare. The surveys may not pinpoint ore, but give information on the location, occurrence, distribution, and structure of the iron-bearing rocks or associated formations. Magnetic surveys also give assurance of the continuity of formations between outcrop or drill holes.

The geological mapping and magnetic surveys are commonly followed by core drilling or other sampling methods. Drilling is the usual way to sample an iron deposit with samples sent to a research laboratory for analysis and process testing. Microscopic studies, both thin and polished section, should be done as soon as samples are available from outcrop or drill samples. It is important that variations in ore types, the mineralogy, and texture of iron-formation lithologies be recognized and their potential effect on concentratability determined. It is a geologist's responsibility to take the microscopic and research test information to the ore body and to show the distribution of ore grades and ore types within the deposit.

Gravity surveys should be considered as an exploration method if the iron deposit is nonmagnetic or where a magnetic survey gives insufficient or confusing results. There may be a sufficient density contrast between iron ore or iron-formation and wall rock to permit a reasonable correlation of the gravity readings with the size, shape, and structure of the deposit.

Down-the-hole magnetic susceptibility measurements may be a relatively inexpensive and effective way to obtain information on the magnetite content of the ore. Saturation magnetic measurements may be used in the laboratory to determine magnetite content of samples.

In dipping iron-formations, deviation of drill holes from the planned direction and inclination is common and may result in significant errors if the deviation is not recognized and corrections in location made on maps and sections. Gyroscopic controlled surveys of drill holes should be used as magnetite in the iron-formations prevents the use of other compass deviation methods. These surveys can be made on a contract basis with well service companies. Hole survey records show the inclination and the location of the drill hole from collar to bottom with a very small potential survey error.

Siderite Ores—Siderite iron ores of Archean age occur

in a number of deposits in the Michipicoten district, Ontario, Canada. The siderite deposits are present as lenticular bodies that form the basal member of the Helen iron-formation, which appears to conformably overlie acidic volcanics and to be overlain by flows of intermediate composition. The Helen iron-formation is divided into three members that from the base upward are (1) siderite member, (2) pyrite member, and (3) banded silica member. The siderite member is composed of a fine-grained, gray-white to tan siderite with some disseminated pyrite and rare thin chert layers. Where of ore grade, the siderite contains from 33 to 37% Fe. It is sintered to remove CO₂ and S and to yield an oxide product as a shipping grade ore. The oxide sinter commonly contains about 50% Fe, 11% SiO₂, 1.7% Al₂O₃, 2.8% Mn, and 0.02% P. This ore is partly self-fluxing, with about 4% CaO and 6.8% MgO. Additional CaO may be added to give a super-fluxed ore with about 18.5% combined lime and magnesia, which reduces the iron content to about 48% Fe.

The major differences between the occurrence of the Helen type iron-formation ores and other Precambrian cherty iron-formation ores are (1) the segregation of the iron-formation into three distinct members with a significant part of the iron present in the siderite member, (2) the common occurrence of pyrite in the siderite ore and in the pyrite member, and (3) the occurrence of a large amount of bedded silica with a low iron content as the banded silica member. Most Precambrian cherty iron-formations contain very little pyrite and have the silica and iron closely linked as alternating silica-rich and iron-rich laminae or layers.

The Helen iron-formation and its members are lenticular on a local and a regional scale. The siderite member ranges from very thin to a maximum of 106 m (348 ft) at the Helen mine. Commonly the ore bodies are less than 60 m (200 ft) in maximum thickness. The pyrite member ranges from very thin to a thickness of 3 to 9 m (10 to 30 ft), but it is about 36 m (120 ft) thick locally in the northeastern part of the district. The banded silica member also ranges considerably in thickness from absent to 300 m (1000 ft) with a common range of from 30 to 60 m (100 to 200 ft).

The Michipicoten district is the only area where Precambrian siderite ore bodies are being mined. A number of deposits of small or rather low-grade sideritic carbonate bodies occur in other parts of Canada in Archean rocks, such as the Woman River area, the area south and east of Lake Abitibi, the Kirkland Lake, and Swayze areas.

Exploration for siderite ores follows a rather normal pattern that includes geological mapping, airborne magnetic surveys, detailed ground magnetic surveys, some local gravity surveys, and core drilling. Geological mapping can indicate the possible location of the siderite member, which commonly has limited outcrop, so this zone can be tested by other methods. An airborne magnetic survey commonly shows the location of the iron-formation often by the magnetic signature of the associated rocks. Ground magnetic surveys run in conjunction with detailed geological mapping give more specific magnetic information that may be related to the associated volcanic rocks. A few gravity surveys were run in past years with limited success. Problems associated with this method are the limited gravity contrast, terrain corrections needed, small size of the target areas, variable thickness of overburden, and rather high cost. While there is no record of the use of electromagnetic survey methods, they might be considered as the occurrence of disseminated and/or massive pyrite should give a recognizable response. Diamond core drilling commonly follows detailed geological and magnetic

survey work to determine the thickness, distribution, and grade of siderite bodies.

Ironstone Ores: Ironstone ores are iron-rich sedimentary deposits composed of oolitic to granular hematite and/or goethite with varying amounts of carbonate and iron silicate minerals that are intercalated with sandstone, shale, carbonaceous shale, siltstone and limestone in rocks from Late Precambrian to Tertiary in age. Movable ironstone beds range from 2 to 7 m (7 to 23 ft) in thickness. The iron-bearing beds are often lenticular both along strike and down dip. The minerals in ironstone ores may be hematite, goethite, siderite, chamosite, iron-rich chlorite, and calcite, with a considerable range in content of the several minerals. They also contain a variable content of admixed sand, silt and clay, which together with the limy component gives a range from siliceous to self-fluxing ore. Ironstone ores have a rather high phosphorus content that ranges from 0.2 to 0.8% but may sometimes exceed 1.5%. Ironstone ores contain from 25 to 35% Fe, 4 to 15% SiO_2 , 3 to 8% Al_2O_3 , 2 to 15% CaO, and 0.2 to 0.8% P. Some deposits, as at Wabana, Newfoundland, Algeria, Morocco, and in the leached outcrop zones of other deposits, have an iron content that ranges from about 45 to 55% Fe. Even in the better grade ores, the SiO_2 , Al_2O_3 , CaO, and phosphorus contents are commonly rather high.

Exploration for ironstone ores usually has started from outcrops or iron-rich float ore visible at the surface. Work continues with geological mapping to show the stratigraphy and structure of the ore-bearing zone and of the associated formations. The ore zone is tested at the surface by pits and trenches and by drilling to show the distribution, thickness, and grade at depth.

Clastic Iron Ores: Iron-rich clastic sediments and sedimentary rocks deposited as sands and gravels have a worldwide distribution as modern and ancient beach, river, alluvial fan, and terrace deposits. Clastic iron deposits as unconsolidated sediments have a wide distribution, but only a few occurrences have sufficient size, grade, and availability to be of commercial interest. Beach and terrace deposits have been mined on a small scale in Japan for centuries with a minor production continuing. Deposits on the West Coast of North Island, New Zealand, are being mined and concentrated for domestic use and for export. The ore occurs on modern beaches and raised Pleistocene terraces. Iron is present as grains of titanomagnetite that contain about 7 to 9% TiO_2 and 0.36 to 0.40% V_2O_5 . The titanomagnetite content in the sands ranges from small to 40 to 45%, with a lower commercial limit of about 8%. A very large alluvial fan type titaniferous magnetite-bearing deposit at Klukwan, Alaska, has been explored but not mined. Erosion of an extensive titaniferous magnetite-bearing mafic and ultramafic body has formed a large alluvial fan that is about 2.4 km (1.5 miles) long and about 0.8 km (0.5 mile) wide which contains about 12 to 13% iron as titaniferous magnetite grains in the fan and in iron-bearing rock fragments. Open pit mining and large scale concentration of the alluvial fan material after grinding and magnetic separation could yield an iron ore pellet that would contain from 64 to 65% Fe and 1.2 to 1.4% TiO_2 . Thus the unconsolidated, modern clastic ores range from deposits in which the iron minerals are free from matrix to deposits where the iron minerals are still enclosed within rock fragments.

The paleo-clastic iron ores are commonly compact, more or less cemented, sedimentary rocks. Iron ore deposits of this type were formed by erosion of cherty iron-formation during the Precambrian and on the Mesabi Range, Minne-

sota, during the Cretaceous. The Mesabi Range Cretaceous ores were mined by open pit methods often as a part of a larger ore body within the iron-formation. Marquette Range deposits are small, with limited production. The Gamagara ores in the Sishen Region, South Africa, may be the largest known deposits.

Magnetite or titaniferous magnetite sand deposits may be explored in a preliminary way using an airborne magnetometer survey. A commercial deposit should give a weak but recognizable response. The physical exploration of unconsolidated, clastic iron ores generally is done using methods common to other placer deposits. The distribution of the potential ore areas is mapped, and then tested by drilling, test pitting, trenching, and possibly by shaft sinking. Drilling is done using a churn or a hammer drill. The sample validity is maintained by driving casing with the sample taken from within the cased hole. Care must be exercised to be certain a reliable sample is obtained. Exploration problems vary considerably and are related to the possible depth of the deposit, water conditions, and the size of the clastic materials.

Exploration for paleo-clastic deposits requires an understanding of the probable depositional environment, and the geological history after deposition. Geological interpretation of the likely sedimentological conditions is of primary importance. Since the most common ore mineral is hematite, with possibly some goethite and magnetite, magnetic surveys may or may not give useful information. As a general rule, magnetic surveys should be made using airborne and ground surveys to assist in broad geological interpretations and specific target selection. Core drilling is done to obtain samples for analyses and testing and to determine the character and the extent of the deposits.

Magmatic Iron Ores

Iron ores that form as a result of magmatic processes include Kiruna type ores and titaniferous magnetite deposits. The Kiruna type deposits are an important iron ore source whereas the titaniferous ores are of minor importance as a source of iron and are mined mainly as a source of titanium or vanadium.

Kiruna Type Ores: An interesting and diverse class of magmatic iron ore bodies is grouped together as Kiruna type deposits. They include deposits in the Kiruna district, Sweden, the Pea Ridge, Iron Mountain, and Pilot Knob deposits, Missouri, the Cerro Mercado deposit, Mexico, and a number of iron deposits such as the Algarrobo, Tofo, and the El Laco deposits in Chile. The Kiruna type ores are composed dominantly of magnetite and hematite commonly with an appreciable phosphorus content in apatite. The shape and size of the bodies varies widely from the very large tabular sill-like body at Kirunavaara, Sweden, which is 4400 m long (2.73 miles), averages 90 m (295 ft) wide, and is known to a depth of over 1500 m (4900 ft), to small veinlets, stockworks, and dikes, and to a deposit considered to be a surface flow at El Laco, Chile. These deposits are all associated with igneous rocks of intermediate to acidic composition, often show intrusive relationships with the associated rocks and show more or less alteration of the country rock. Magnetite is the most important iron ore mineral with varying amounts of hematite. Some deposits that contain mainly hematite are included in this class such as those at Iron Mountain, Missouri, which contain about 80 to 95% of the ore as massive hematite with some platy hematite and 5 to 20% magnetite (Murphy and Ohle, 1968). The Kirunavaara magnetite ore contains from 60 to 69% Fe, 0.01 to 2.3% P, 0.7 to 3.7%

SiO_2 , 0.13 to 0.6% Al_2O_3 , and 0.13 to 0.23% U_2O_5 (Parak, 1975). The Pea Ridge ore contains from about 45 to 60% Fe and a rather constant phosphorus content even though the magnetite-hematite ratio ranges from dominant magnetite to dominant hematite. Many of the Kiruna type iron ore deposits require concentration to remove phosphorous and to upgrade the ore to a high quality shipping product.

Usual exploration technique for Kiruna type deposits includes geological mapping, airborne and ground magnetic surveys, and gravity surveys. The ores in Sweden, Cerro Mercado, Mexico, at Iron Mountain and Pilot Knob, Missouri, and a number of Chilean deposits were discovered in outcrop and studied and explored by detailed followup geological and geophysical work. The Pea Ridge deposit and a number of other undeveloped iron ore deposits in Missouri were discovered by magnetic methods. The existence of the Pea Ridge deposit was indicated by an airborne magnetic survey flown in 1950 and found by drilling in 1953. The deposit occurs below about 396 m (1300 ft) of Paleozoic sedimentary rocks. Gravity surveys were used as an important exploration and evaluation method at the Iron Mountain and Pilot Knob deposits (Leney, 1956). The northwest ore body at Iron Mountain which is essentially a nonmagnetic, hematite ore was found by a gravity survey much later than the vertical, main ore body which was discovered by drilling under a strong magnetic anomaly. The northwest ore body occurred at a shallow depth and was mined by open pit methods whereas the vertical ore body was mined by underground methods. The Iron Mountain geophysical studies illustrate the importance of using both magnetic and gravity methods where nonmagnetic hematite ore may occur.

Titaniferous Magnetite Deposits: Titaniferous magnetite deposits have a worldwide distribution in basic igneous rocks, commonly gabbros or anorthosites, and in some metamorphic rocks of basic composition. These deposits occur as tabular to irregular shaped bodies or seams and veinlike areas or in layered mafic intrusives as tabular stratigraphic zones that range from massive to disseminated. The iron content ranges from less than 20 to over 60% with from 1.5 to 35% titanium and 0.1 to 2.0% vanadium. Titaniferous magnetite deposits have limited use as a source of iron ore because of the relatively high titanium content. The main purpose of mining these deposits is as a source of titanium or vanadium. There is more or less use of the magnetite byproduct. Iron is produced at the Sorel plant after processing the Allard Lake, Quebec ore. Some of the magnetite concentrate from the Sanford Lake deposit in New York is used as iron ore. Deposits in the Bushveld Complex, Republic of South Africa, are mined for their vanadium content. Titaniferous magnetite is a primary iron ore from beach and terrace deposits but not from lode deposits.

Contact Metasomatic Deposits (*Magnetnaya Type*)

An important class of iron ore deposits occurs as replacement bodies, commonly in limestones, at or near contacts with intrusive igneous rocks. These ores usually occur as massive, magnetite, or magnetite-hematite or hematite-magnetite bodies, often with common skarn minerals and small quantities of associated pyrite, pyrrhotite, and chalcopyrite. The skarn minerals include pyroxenes, amphiboles, garnet, epidote, chlorite, scapolite, apatite, and calcite. The ore bodies are often irregular to tabular in shape and range in size from deposits of a few thousand tons to several hundreds of millions of tons. Commercial deposits usually contain a minimum of a few million tons of ore grading from 35 to 55% Fe. These ores commonly require processing to

upgrade the iron content and remove sulfur, copper, other base metals, and slag-forming elements to yield a high-grade, low-impurity product. Some deposits yield salable byproduct: copper and other metals.

Many of the known contact metasomatic iron ore deposits were found by direct observation of extensive areas of float ore and outcropping ore. Exploration of these deposits included geological mapping accompanied by magnetic surveys and core drilling.

Airborne magnetic surveys either made for iron ore exploration or as regional surveys have resulted in the discovery of a number of deposits. Exploration for blind contact metasomatic iron deposits may follow a rather classic pattern of (1) geological reconnaissance to select areas that appear to have a favorable geological environment with correct types of igneous intrusive and host rocks; (2) regional airborne magnetic surveys; (3) interpretation of the magnetic information with the selection of potential target areas; (4) detailed geological mapping and ground magnetic surveys possibly accompanied by gravity surveys; and (5) drilling. Replacement deposits commonly have a marked magnetic and density contrast with the associated country rock which permits an interpretation that includes a reasonable estimate of the size, shape, depth, probable reserve tonnage, and, with some drill core analysis data, the grade of the deposit.

Massive Iron Ores in Cherty Iron-formation

Massive, high-grade iron ore deposits occur in cherty iron-formations in geological situations that suggest an origin by a replacement process where silica has been replaced by hematite or magnetite and in deposits occurring at or near paleo-erosion surfaces that appear to be metamorphosed paleo-Lake Superior type ore bodies. The replacement type iron ores are commonly composed of compact, steel gray or crystalline, micaceous, or granular hematite or a mixture of hematite and magnetite or in a less common occurrence as granular magnetite. The common associated minerals are quartz and iron silicates. Ore bodies of replacement type have a considerable range in shape, size, structural relationships, and distribution within the cherty iron-formation. Deposits that occur at or near ancient erosion surfaces contain iron ores similar to replacement ores. There are conflicting opinions on their origin. The two ore occurrences will be considered together as both types of deposits have similar exploration and evaluation problems.

Iron ores at the Soudan mine, Minnesota, occur at the ends of lenticular belts of jaspilite iron-formation or are associated with folds. There is no recognized relationship of the ore to structures that would permit access of solutions involved in the replacement process although evidence of the replacement of chert layers by hematite is very clear. Deposits of granular, crystalline hematite occur in the axial areas of folds in parts of the Quebec iron ore district between the Matonipi Lake area and Labrador border and south of the Orinoco River between the delta area and the Caroni River. These iron ore deposits are commonly lenses and pods not large enough to be of commercial interest. The associated iron-formation is of the Itabirite type and country rocks are commonly gneiss.

Certain of the *Hard Ore* deposits in the Marquette Range, Michigan, are at or near a Precambrian paleo-erosion surface at the top of the Negaunee iron-formation. The Marquette Range *Hard Ores* were mined extensively in the Ishpeming-Negaunee area and are largely exhausted.

Exploration for hematite-rich replacement or Paleo-Lake Superior type iron ores may be difficult if they do not outcrop

and do not contain sufficient magnetite to create a recognizable magnetic signature. Many deposits contain the same iron minerals as the associated iron-formation and are, difficult to locate using any geophysical method. A considerable density contrast may occur, so gravity surveys may be used to locate near surface deposits. However, gravity surveys are expensive, slow, and not easily adapted to the required accuracy as a reconnaissance method. After the initial discovery and the likely geological relationships to structures or to a paleo-surface are observed, drilling is the common followup exploration method. As an example, at the Soudan mine much underground drilling was done to test geologically favorable targets such as projected trends of known ore and favorable areas at the ends of iron-formation lenses. Exploration for Marquette Range *Hard Ores* was started from outcrop observations followed by geological mapping and drilling. Underground geological mapping, drilling, and a following of the ore continued during the long mining history. The principal method for successful exploration appears to be competent geological mapping and interpretation of the ore relationships followed by a carefully monitored drilling program.

Residual Iron Ores

Iron oxides are commonly formed at the earth's surface by the weathering of iron-bearing rocks. Where the oxide accumulations are of sufficient size and iron content they constitute sources or potential sources of iron. Five classes of iron ore deposits are formed by weathering processes: Lake Superior type ores, oxidized banded iron-formation-*OXIBIF* ores, Canga and River Terrace ores, Brown ores, and Lateritic ores. A large part of the iron ore moving in international trade is produced from naturally occurring, merchantable or concentrating grade, Lake Superior type iron ore deposits associated with Precambrian cherty iron-formation.

Lake Superior Type Deposits: Iron ores formed by the oxidation of iron minerals and the leaching of silica from cherty iron-formations with the residual accumulation of iron oxides have been extensively mined in Michigan, Minnesota, and Wisconsin, which resulted in these ores being termed *Lake Superior type* ores. They are now produced on a large scale in Australia, Brazil, India, Liberia, Mauritania, Republic of South Africa, USSR, and Venezuela. Large undeveloped deposits are known in Brazil and in Gabon and Guinea in Africa. Lake Superior type ores occur in deeply weathered areas at the present land surface and in favorable geological situations to considerable depth below the surface. In Michigan at the Mather mine, Lake Superior type soft ores were mined to depths of about 1 070 m (3500 ft) with ore known to occur to depths of over 1 525 m (5000 ft). On the Mesabi Range in Minnesota, slump structures are associated with the iron ore bodies. These structures formed because of the removal of about 30 to 45% of the original iron-formation volume during leaching of silica.

In the Lake Superior Region the base grade ore is assumed to contain 51.5% Fe with price adjustments made for ores that contain above or below this percentage of iron. Most merchantable ore and iron ore concentrates contain a higher iron content than the base grade. As an example, in 1970, 25 Mt of natural ore shipped from the Lake Superior region contained an average of 54.26% Fe, 8.87% SiO₂, 1.19% Al₂O₃, 0.61% Mn, 0.08% P, and 6.85% moisture.

Since about 1910, certain partly leached, natural iron ores have been beneficiated by simple methods such as washing, screening, and by gravity methods. These ore materials

are termed *concentrating grade natural ores*. They are commonly included with the Lake Superior type ores as the geology of occurrence is similar and the two ore types often occur together with gradational relationships. The difference between the two ores is the efficiency of the removal of silica by leaching. The silica present in the concentrating grade ores occurs in a physical condition that will permit its removal to an acceptable concentrate grade by gravity beneficiation methods without extensive grinding.

Exploration for Lake Superior type, merchantable, and natural concentrating grade iron ores requires an understanding of the favorable geological conditions for ore occurrence. These deposits form as a result of oxidation and the leaching of silica from cherty iron-formation with the residual accumulation of iron oxides. Ore bodies commonly occur in areas that are most favorable for extensive ground water movement. Favorable exploration targets may be at the present land surface, along paleo-land surfaces, fault zones, or associated with troughlike structures that could channel ground water flow. Favorable geological structures include a variety of situations that will concentrate water movement such as synclinal folds, fault zones, troughlike zones at dike intersections and strongly jointed and fractured areas. During oxidation and leaching, primary iron silicate, iron carbonate, and magnetite are converted to hematite and goethite, with very minor maghemite and lepidocrocite and with associated varying, small amounts of residual clay, quartz, and manganese oxides. Ore development can be considered a part of the weathering process of a special rock, iron-formation during an extended, intense weathering cycle.

Exploration for Lake Superior type and concentrating grade natural ores is based on the accumulation of information on potentially favorable areas for intense, long-term leaching action by ground water. As in most exploration programs, geological mapping and direct field observations are used as fully as conditions permit. Field observations are commonly supplemented by magnetic surveys very early in the exploration program as some magnetic signature is usually identified. The usefulness of magnetic surveys varies considerably from merely locating the cherty iron-formation host to very directly indicating potential ore areas. Since the Lake Superior type ores and concentrating grade natural ores are formed by oxidation and leaching, the magnetic readings over ore bodies commonly are low relative to the associated iron-formation. Favorable exploration sites are located in low magnetic anomaly areas. A common exploration sequence following field studies is to conduct an airborne magnetic survey at a low terrain clearance of about 120 m (400 ft) and a line spacing of about 400 m (0.25 mile) with favorable areas shown by the airborne survey covered by ground magnetic surveys. The magnetic line and station spacing selected should give adequate detailed magnetic information to permit the geological interpretation of the magnetic readings. The ground magnetic survey area should be large enough to allow calculation of depth, width, and attitude of the potential ore-bearing structure.

Gravity surveys have a limited, though at times very useful, purpose in the exploration for Lake Superior type or concentrating grade natural ores. Since these ores are often rather porous, with a sizable moisture content, they may have a small, sometimes almost zero, gravity contrast with the enclosing rocks. This can severely limit the use of gravity methods. In some areas, such as in parts of the Cuyuna Range, Minnesota, regional gravity surveys have been used as an important geophysical method to supplement magnetic methods. The cherty iron-formation on the Cuyuna Range

has a very weak magnetic response so gravity methods were used to trace the distribution of the iron-formation and to assist in the selection of potentially favorable areas.

Geological mapping is an important initial exploration approach used for iron ores that occur at the present surface in areas with a reasonable amount of outcrop. The mapping is often done after an airborne magnetic survey which commonly shows the location of the iron-formation. Airborne and ground magnetic surveys should be used in conjunction with geological mapping as they will give valuable information regarding the location, distribution, structure, and the character of the iron-formation. Field observations that can be made include variations in the character of the iron-formation, structural relationships, and the nature of the outcrop ore. The presence or absence of outcrops also may be helpful in the search for guides to the recognition of potential ore areas. The observed geological and magnetic data often indicate specific possible ore areas that should be tested by drilling.

Magnetic surveys are usually the principal exploration method used in areas with little or no outcrop. An exploration program in such areas commonly starts with a regional airborne magnetic survey of the selected area. This survey is usually run at about 400 m (0.25 mile) flight line spacing with low ground clearance. The magnetic data are then interpreted to show the location of the iron-formation, structural relationships, and potentially favorable areas. These areas are covered with ground magnetic surveys using appropriate line and station spacing. The possible ore areas are then tested by drilling.

An important aspect of any iron ore exploration program is the continuing reappraisal and evaluation of the available information as new and better data are received. In many cases interpretations made early in a program may need substantial adjustment as the work progresses. It is also important that as complete a drill record as possible be maintained in the form of drill core. Split drill core should be retained for restudy in the light of new facts generated as the investigations proceed. Core logging should involve the most capable geologists, as the best possible core interpretation is essential to a successful program.

OXIBIF Ores: Oxidized banded iron-formation ores include all concentrating grade cherty iron-formation material composed of earthy or very fine grained, compact, or steely hematite with more or less associated goethite interbedded with cherty quartz-rich layers. Characteristically these ores are the result of secondary oxidation with more or less leaching of cherty iron-formation. They could be termed "weathered cherty iron-formation." Marsden (1978) used the acronym OXIBIF for these ore materials as the term oxidized banded iron-formations is used to identify a variety of non-ore cherty iron-formation. As defined, the acronym is to be applied only to concentratable oxidized, banded, iron-formation materials. These ores require fine grinding to yield a commercial grade iron ore product.

OXIBIF ores are commonly red-brown in color and prominently layered with iron-rich layers dominantly hematite or goethite interbedded with brown to red-brown cherty quartz. The thickness of the layering varies from a millimeter to several centimeters with many visible layers observed in a mine bank or outcrop from 5 to 15 cm (2 to 6 in.) or more thick. These ores may be rather porous and friable to compact and massive depending on the degree of weathering and the original oxide, silicate, and carbonate content. The iron oxides and cherty quartz are often fine grained so a very fine grind may be required to give effective liberation of the iron

minerals. Commonly all primary iron silicate and carbonate minerals and magnetite have been oxidized, although a small amount of magnetite may be present. Soluble materials have been removed, leaving mainly Fe_2O_3 or $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$, SiO_2 , and Al_2O_3 . Extensive deposits of oxidized iron-formations occur in the Lake Superior region, in the Labrador trough, Canada, in the Thabazimbi region, South Africa, and may occur in other areas of the world. At this time OXIBIF ores have a limited commercial development as more economic iron ore deposits are available.

OXIBIF iron ore is currently being mined and processed at the Tilden mine, Marquette Range, Michigan. The ore is ground very fine, about 90% minus 500 mesh, to give effective liberation of the iron minerals; then the ore is concentrated using the selective flocculation-flotation system.

OXIBIF deposits are commonly weakly magnetic to essentially nonmagnetic, which often limits the use of magnetic methods in their exploration to surveys designed to show their general location and extent. Exploration for OXIBIF ores relies on geological mapping with accompanying magnetic surveys, both airborne and ground, followed by drilling and laboratory tests. It is worth the effort to attempt to determine whether detailed magnetic surveys are an aid in the determination of the distribution of ore quality iron-formation materials. The recognition of the concentratability of the oxidized banded iron-formation is based on laboratory testing. The extent and occurrence of OXIBIF materials requires a careful geological evaluation of the detailed stratigraphy and structure of possible ore areas. The exploration work must include a carefully planned, rather detailed sampling program, usually done by drilling followed by specific research testing of samples. The results of the sampling and testing is interpreted into the distribution of ore types within the deposit. A geological understanding of laboratory test results is most important in the evaluation of OXIBIF deposits.

Canga and River Terrace Deposits: Iron oxide crust deposits that contain variable amounts of cherty iron-formation and iron ore fragments cemented by goethite and hematite are common to tropical regions and in Western Australia where there are extensive areas of exposed cherty iron-formations. These deposits are termed *Canga* in Brazil. This term may also be applied to similar deposits that occur extensively as residual crusts of hematite and goethite on outcropping iron-formation in the Hamersley region of Western Australia. Canga is defined as a surficial crust commonly composed of iron-formation or iron ore fragments cemented by iron oxides. The content of fragments and secondary iron oxides that precipitated from solutions to form a cement varies. In both Brazil and Australia the Canga crust is believed to be of Tertiary age. In the Hamersley region the Tertiary Hamersley erosion surface is more or less eroded with the hard, oxide, ferricrete crust acting as a protective cap to hills.

In the Robe River, Duck Creek, Beasley River, and Fortescue River areas in the western part of the Hamersley Range there are extensive River Terrace iron deposits that are extensions of Canga accumulations. These River Terrace deposits occur as valley bottom iron oxide crusts composed of pisolitic and cellular goethite, with associated detrital materials. These deposits are described by Brandt (1973) as: "The derived type deposits have clearly originated from both mechanical and chemical weathering of jaspilites, whereby detrital accumulations were formed and were subject to supergene leaching of silica, hydration of original hematite and other iron minerals, and the deposition of much limonite

cementing and replacing the original rock fragments. Their formation has involved the downslope transportation of enormous amounts of iron as detritus, in solution, or both. The deposits range from limonite-cemented scree on slopes which are sometimes continuous with in situ canga cappings on hilltops, to thick valley-floor accumulations of massive and pisolitic limonite without detrital material." The eroded pisolitic, river terrace deposits often form extensive mesa-like hills capped by an iron oxide crust often about 30 m (100 ft) to a maximum of about 60 m (200 ft) in thickness. The Canga and river terrace deposits commonly contain from 40 to 60% Fe, 4 to 10% silica, and have a 10 to 12% ignition loss. These ores are being mined in the Robe River area.

Since Canga and river terrace deposits occur as surficial crusts, they are exposed on hill slopes, and along ravines and streams so their occurrence and distribution can usually be mapped in the field or on aerial photographs. The thickness of the deposits and grade of the material is determined by drilling.

Brown Iron Ore: The term *brown ore* is applied to a group of iron ores that occur as residual accumulations from the weathering of a number of iron-bearing rocks. These include limestones and dolomites, greensands, sideritic bodies and rocks, and veins containing iron sulfides. Brown iron ores have a wide distribution and in the past were important sources of ore for local iron furnaces. They are now of limited importance for a variety of reasons, including their common small size, variable chemical composition, often rather high silica content, the exhaustion of many of the larger deposits, the concentration of iron and steel production into large integrated plants, and the ready availability of high-grade iron ore on a worldwide basis.

Discovery and exploration of brown iron ores is highly dependent on surface indications of possible ore occurrence which often consists of float pieces of iron oxide. The likely target areas are then sampled by test pits or trenches or by drilling. Leney (1966, p. 410) reports "Standard resistivity surveys with an arrangement of current and potential probes at the surface to measure resistivity of the ground have had some success in prospecting for shallow flat-lying ore bodies. They have been applied effectively in Minnesota's Spring Valley district to locate residual pockets of limonite-goethite ore occurring on a limestone surface under shallow cover, but so far have not been able to compete in cost with simple auger drilling. In Missouri, resistivity surveys are reported to be useful in measuring the thickness and lateral extent of ore-bearing clay residuum in brown (goethite-limonite) ore deposits."

Lateritic Iron Ores: The lateritic weathering of ultramafic rocks including dunites, peridotites, and serpentinites in tropical and subtropical regions may develop residual iron oxide deposits that contain from 40 to 55% Fe. The iron-rich surficial deposits range in thickness from less than a meter to over 100 m (328 ft) with extensive areas underlain by deposits from 3 to 10 m (10 to 33 ft) thick. These laterite deposits are not a commercial iron ore at present because of the relatively high chromium and nickel content. Lateritic iron ores were mined in Cuba from the early 1900s until about 1950 and were used to make chromium-nickel steel. Lateritic iron deposits are composed of a rather massive, red-brown, hematite-goethite *crust ore* zone with a yellow, powdery limonitic zone below that rests on an irregular weathered bedrock surface. These ores commonly contain from 45 to 55% Fe, 8 to 12% Al_2O_3 , 2 to 8% SiO_2 , 0.2 to 2.5% Cr, 0.4 to 2.0% Ni, 10 to 30% moisture, and 6 to 14% combined

water. The powdery ores are very porous and high in both moisture and in combined water.

Since the lateritic deposits occur at the surface, their general distribution can often be determined by surface mapping with the depth determined by drilling, using a hand auger or power auger, trenching, and test pitting. The drill holes usually will stand as open holes, often for a number of years without caving, which makes sampling relatively easy and accurate.

MAPS AND MAPPING

Maps are essential to all exploration projects. The most basic group of maps is prepared and used for location control. These maps serve as base maps upon which other information is recorded either in the primary gathered form, or as compiled and coordinated data, to present results of the work in a readily usable form. The special maps are prepared to meet the needs of geologists, geophysicists, engineers, planners, evaluators, and mine operators at various stages during exploration, development, evaluation, and mining. Map scale selection is a fundamental decision of importance to the project. The map scale should be appropriate to the amount and type of information to be shown as well as to the purpose and expected use of the map. The map scale selection process should include the people developing the map and those who will use it. It should also fit into a rational system. A maverick scale is an unwelcome nuisance. The size of maps produced should also receive early attention so maps are convenient to use and easy to file. McKinstry (1948) suggests maps of 91×102 cm (36×40 in.) as a maximum and 46×61 cm (18×24 in.) as a minimum size. Another early decision made during an exploration program is the orientation of the survey control system. This is often the azimuth direction of the grid control for geological mapping and geophysical work. The implications of grid orientation with regard to future drilling, development, and mining should be considered as the first control work is done.

A review of available maps should be one of the first steps in an exploration program as location control is essential at all stages of the work. There are a variety of government-prepared maps and aerial photographs available that may be used during the initial phases of the work. Modifications of scale of regional and topographic maps and aerial photographs can be made to suit the geologist's needs during preliminary phases of a program. Early in an exploration program, maps made to suit the specific project needs will be required. These maps can be made as a part of the work program or under contract with one of a number of companies. The ready availability of map preparation services that can develop maps at a desired scale and accuracy is a modern reality. After selection of a contractor the most important decisions concern scale, accuracy, contour interval for contour maps, area to be included, and the time the work should be done. The contractee should exercise a reasonable level of supervision to insure the validity and accuracy of the completed work.

In iron ore exploration the likely occurrence of local magnetic anomalies that may influence field mapping should be recognized. The severity of the problem varies considerably from conditions where major compass deviations occur to almost no visible influence from the iron deposits. In strong magnetic deviation areas, a sun dial compass is useful in geological mapping for the accurate determination of strike and for direction control on survey lines. The sun dial compass is based on the principle of a sun dial to give the time of day, which is reversed to use the known time of day to

give a true north direction at the reading point. Mapping iron ore deposits follows the usual methods applied by geologists and engineers. The geological work involves recording of special ore characteristics such as the mineralogy, texture, and the physical nature of merchantable ore and the mineralogy, texture, grain size, stratigraphic variations and zonation, weathering characteristics, potential minability, and concentratability for concentrating grade ores.

GEOFYSICS

The application of geophysical methods to the exploration and evaluation of iron ore deposits is accepted as a standard procedure. Geophysical systems measure properties of minerals either in the ore body or in associated rocks that can be interpreted to give useful information regarding iron ore deposits. The successful application of a particular geophysical method depends on the presence of distinct, measurable properties interpreted in a way that assists in location and understanding of an iron ore body. The several methods used can often furnish recordable, objective information that complements and supplements other methods of study. Geophysical studies may be used effectively from the initial selection of possible exploration areas, throughout the exploration and development program, and sometimes during the mine operation. Geophysics should be considered as more than just an exploration tool as it may have other useful applications.

Studies of local variations of the earth's magnetic field using magnetic methods are the basis for much of the geophysical work related to exploration for iron ore. Other geophysical methods such as gravity, radiometric, electrical, or seismic have limited roles and when applied, usually have specific applications in contrast with the almost universal application of magnetic methods. A contributing factor to the wide use of magnetic methods is the fact that these surveys commonly give valuable information concerning regional geology such as the types of rock present, their distribution, continuity, and structure. A regional, broad purpose magnetic survey can often indicate the location of iron-bearing rocks and may in some cases show the location of iron ore bodies. The importance of the magnetic method in regional reconnaissance surveys cannot be overemphasized as it permits the use of airborne magnetic surveys as a primary screening system in the exploration for iron ore deposits. Airborne survey methods also have the advantage that the reconnaissance phase of the work can be done without the confining aspects of property control and access. Other airborne geophysical systems have almost no direct application to the exploration for iron ore, but electrical and radiometric methods are often run with regional magnetic surveys as the additional cost is relatively small and the exploration company may be able to use these data to look for other types of mineral deposits.

Magnetic Methods

Magnetic geophysical systems measure variations in the earth's magnetic field caused by differences in the magnetic characteristics of the underlying rocks. The earth's field is a spontaneous force that consists of the natural force field as modified by geological bodies. In the International System of Units (SI), the unit of measurement for a magnetic field is the tesla (T). The earth's magnetic field has a magnitude of about 0.6×10^{-4} T at the surface, so measurements of the field usually are reported in more convenient units of nanoteslas (nT); $1 \text{ nT} = 1.0 \times 10^{-9}$ T. Older magnetic surveys reported field measurements in gamma or Gauss

units and may readily be converted to SI units by the relationships $1 \text{ nT} = 1 \text{ gamma}$ or $1 \text{ nT} = 0.1 \times 10^{-6}$ Gauss. The magnetic method may be used in a wide range of field circumstances in the air, on land or water, in drill holes, or on ore samples in the laboratory. There is a considerable range of available instrumentation, recording accuracy, and logistics of application, which eventually affects costs of conducting a magnetic survey. This flexibility of application is one of the factors that favors its use.

Rocks containing unusual amounts of minerals with ferromagnetic susceptibility are magnetized in the earth's field and minerals with a remanent magnetization maintain an independent magnetic field. Both distort the earth's normal field. Measurements of the magnetic field are compared with the normal field or relative to a selected magnetic field reference point. This comparative relationship is used to show local variations caused by anomalous rock bodies. Magnetic readings are taken over a grid pattern or along survey lines. The observed variations or anomalies are interpreted geologically to the likely material and body that may cause the observed magnetic response.

The magnetic method has been used in exploration for iron ore since about 1640 when it was first used in Sweden. The *dipping compass* or dip needle was used extensively in iron ore exploration until about 1950. Since that time a number of types of magnetometers have been developed that are more accurate and easier to operate in the field than the dip needle. The airborne magnetic method for use in exploration was introduced during the period 1946-1950 and has resulted in major changes in exploration for iron ore and other mineral deposits. There are four general types of magnetometers in use that include variometers, flux-gate magnetometers, proton magnetometers (nuclear resonance), and optically pumped or alkali vapor magnetometers. The variometer type instruments include the dip needle, super-dip, Schmidt type magnetometers, and torsion-head type magnetometers. They measure variations within the total magnetic field and can measure either the vertical or horizontal component; commonly, the vertical component is measured. These instruments can measure to a precision of about 10 gammas per scale division. The magnetometers are tripod mounted, which makes them cumbersome to use. The flux-gate magnetometer was developed for airborne magnetic surveys and later adapted to small, very portable units for ground surveys. Ground survey units measure the vertical component with a precision range of 0.5 to 12.5 gammas with a common accuracy of about 5 gammas. The Jolander and Sharpe magnetometers are flux-gate types. These instruments are direct reading, hand-held, do not require azimuth orientation, only coarse leveling, are lightweight, and convenient to use in the field. The proton magnetometers now have a wide use in airborne and ground magnetic surveys. These instruments have a high degree of accuracy and are used in airborne surveys recording at a precision of 0.5 to 1.0 gamma. The portable ground survey instruments are direct reading and measure the total magnetic field. The optically pumped magnetometers include the rubidium and cesium vapor magnetometers that measure the total earth's magnetic field with an accuracy to about 0.001 gamma. They have been developed for use in airborne magnetic gradiometers that measure and record gradients in the earth's magnetic field. This is a new airborne geophysical survey method expected to result in new applications in mineral exploration.

The magnetic properties of rocks, details of the several types of magnetic instruments, survey techniques, magnetic

data processing, and the interpretation of magnetic observations are described in detail in a number of books and references, such as Hansen, et al., Heiland, Nettleton, Parasnian, Vacquier et al., and others. This discussion assumes a basic knowledge of the magnetic method and will focus on the applications to iron ore exploration, evaluation, and development.

Regional airborne surveys made as a part of an exploration for iron ore are usually run with a terrain clearance of about 50 to 150 m (165 to 500 ft) with a line spacing of from 50 to about 500 m (165 ft to about 0.3 mile). This type of coverage results in a good precision of magnetic observation along the flight line and a generally acceptable distance for lateral projection correlation between flight lines. The flight elevation is about minimum for safety and line location control in a fixed wing aircraft. A closer spacing rapidly increases costs without a significant increase in the accuracy needed for a detailed reconnaissance, regional survey. A wider spacing of flight lines is acceptable for some exploration situations but can materially decrease the confidence in lateral projection correlations and may miss magnetic anomaly areas associated with some types of valuable iron ore bodies. Competent geological knowledge is a prime requirement for the interpretation of airborne survey results. The survey data are plotted on isomagnetic contour maps prepared by the contracting survey company. The geophysicist and geologist making the interpretation may wish to examine the flight line data and check the contour control information to see if there may be other ways to connect the observed anomaly areas.

Ground magnetic surveys are run along profile lines, generally perpendicular to the strike of the anomaly area and at a line spacing determined to give adequate information for a study of the anomaly area. For best results, profile lines should be surveyed to give good location control. The magnetic readings are plotted as profile sections and contoured to show the magnetic variations on a map. The magnetic data can be interpreted by standard methods to determine the size, shape, dip, strike, depth below the surface, and probable volume of the anomalous body. Often the probable rock or iron ore type causing an anomaly is known, which reduces the range of likely geological situations that can result in the observed magnetic anomaly. Even when the likely nature of the anomalous body is known, there may be a sufficient number of unknown factors to prevent a unique identification of the cause of the anomaly. Core drilling is usually needed to show the nature of the magnetic material and to permit the interpretation of the magnetic data. Even after drilling, bodies that have a strong remanent magnetization may make the geometry of the anomalous body difficult to interpret.

After an iron ore deposit is located, and sometimes after an iron mine is in operation, detailed magnetic surveys are run to give more accurate information regarding the limits of ore occurrence. In a number of instances the delayed application of magnetic surveys is the result of a need for a better understanding of the contact zone of deposits that have gradational ore boundaries to better define the current economic ore limit. As an example, magnetic surveys were run in the 1950s and 1960s on a number of ore bodies on the Mesabi Range, Minnesota, to more accurately locate the margins of natural iron ore deposits. These surveys permitted a more accurate location of development drill holes needed to show the mine pit wall.

Magnetic measurements in drill holes may be made to define the shape of magnetic bodies cut by the drilling or to

test the possibility that a drill hole may have narrowly missed an adjacent magnetic body. Magnetic observations also may be used to determine the content of the magnetic mineral present. A magnetic susceptibility probe is being used to determine the magnetite content of magnetite taconite intersected by blast holes at the Minntac mine. The results allow a close definition of the contact between waste rock and ore.

Gravity Methods

Gravity methods have a rather restricted application in the search for and evaluation of iron ore deposits. This is in part the result of the highly successful application of magnetic methods, the rather infrequent circumstances where gravity should be used, and in part due to the cost and problems related to gravity methods. Even though little used relative to magnetic methods, gravity surveys can give useful results when focused on specific applications. The successful use of gravity surveys requires a definite, measurable, density contrast between the iron ore body and country rock. It may give highly useful results on ore bodies with a strong remanent magnetization or on deposits that are essentially nonmagnetic. Since gravity measurements are directly related to rock density, gravity surveys can give, under favorable conditions, an approximate indication of the tonnage present in an iron ore body. Regional gravity mapping can also be a valuable addition to regional geological mapping, particularly when used in conjunction with an airborne magnetic survey. Both regional and specific gravity surveys were used successfully during exploration of the North Cuyuna Range, Minnesota, where only vague interpretations of the possible locations of the Trommald iron-formation could be made from magnetic surveys. At Iron Mountain, Missouri, Leney (1966) reports the use of a gravity survey that indicated an extension of iron ore to the south of the known ore body. Gravity surveys were also successfully used during exploration of the Steep Rock iron ore bodies, Ontario, Canada.

Other Geophysical Methods

A number of attempts to use electrical methods in iron ore exploration are reported by Leney (1966). The results from resistivity, self-potential, and other potential and electromagnetic surveys do not suggest an expansion of the use of these methods in the exploration and evaluation of iron ore deposits. They are seldom used although there may be special problems where one of the electrical methods may give helpful results. Resistivity was used with limited success in the exploration for limonitic iron ores that occur as pockets in limestones in the Spring Valley district, southern Minnesota. However, even here the exploration company concluded that geological studies accompanied by auger drilling were much cheaper, and gave equally satisfactory results in ore discovery.

Theoretically, electrical methods could be used as a mapping tool if a strongly conductive body, such as a graphitic slate, has a consistent relationship to a nonmagnetic iron-bearing formation. Also, if factors that affect iron ore minability, such as faults or leached zones, display unique electrical properties, electrical methods may be used to delimit these structures. Even in these situations, magnetic methods should be shown to be ineffective before electrical methods are applied.

The recent development of high resolution, shallow seismic survey equipment has added an important capacity for iron ore exploration. Due to velocity contrasts between most iron-bearing rocks and overburden materials it is possible to construct maps that show the depth of overburden. Some

control drilling is required to insure that the correct velocity interface is selected so the ore-overburden contact is mapped. It seems possible that additional uses may be developed for high resolution seismic methods.

EXPLORATION DRILLING

Drilling is a critically important activity in the exploration and evaluation of an iron ore deposit. Drilling usually follows detailed surface geological and geophysical studies that have shown the possible occurrence of a valuable deposit. A drill program to investigate an ore target has three basic purposes and steps: (1) to show the occurrence of a potentially valuable deposit and give basic information on broad geological relationships and nature of the iron ore; (2) to determine the ore dimensions, chemical and physical nature of the ore, its concentratability, if the ore requires processing to yield a salable product, and to acquire other positive information that will permit a generalized evaluation of the tonnage potential and a preliminary estimate of its commercial feasibility, (3) to obtain sufficient detailed information, by a continuation of drilling and sampling, concerning the distribution of ore types and grades so a fully reliable feasibility study and economic evaluation can be made.

Planning a drill program requires judgments on the appropriate drill pattern, hole spacing, type of drilling and equipment, sampling procedure, elements to be determined by assay, and the research testing needs. A principal concern should be the accurate and efficient determination of the nature of the ore and of the ore body on a cost-effective basis.

The locations of the first few drill holes in a target area are critically important as a common perception within an exploration company is that these drill holes are situated in areas of maximum opportunity for ore discovery. Thus the success or failure of the first few drill holes may determine whether the project is continued or abandoned unless a very well-documented geological evaluation of all factors is presented. At this stage there should be a careful and reasonably complete geological appraisal of the ore potential before a decision is made regarding a partly drilled prospect. This evaluation should include a statement of the likely economic feasibility of the project. It is a waste of time and money to extend work on a deposit that is without commercial merit or to drop a property with a reasonable possibility of commercial value. The need for an early geological view of exploration potential is as valid for iron ore deposits as for other ores.

The importance of a well-considered start should be recognized in preplanning. The preplanning aspect includes the selection of drilling and sampling methods, equipment and drilling pattern, whether vertical or angle holes will be drilled, and if core drilling is done, the size of the core to be taken. The primary concern should be to insure that the drilling products give the proper information. Many geologists believe it is preferable to err on the side of too much detailed information rather than on the side of too little and possibly questionable results. Other geologists are very cost-conscious and emphasize the need to keep the costs low and to show rapid progress in the ore body study and target evaluation. A cost-effective approach to exploration is always needed but this must be coupled with reliable information. Lake Superior type iron ores are often soft and friable with mixed hard and soft layers which makes sampling and data gathering difficult. Thus, preplanning becomes very important so that accurate data may be obtained. In compact, rather uniform solid ores such as contact metasomatic ores

and magnetite taconite ores, a major problem may be the selection of the most cost-effective approach. Since some iron ores are very hard, the critical decision may be how to best obtain accurate core samples using diamond drills that give adequate amounts of material for analysis and testing.

Three general methods are used in iron ore exploration drilling and sampling: core, rotary, and percussion. For each method there is a considerable range in equipment and in the way it is applied. All three systems may be considered in shallow drilling, generally less than 90 m (300 ft) in depth. As a generalization, rotary and percussion drilling methods experience sampling problems in iron ores at relatively shallow depths because of the relatively low density of the gangue component and high density of the iron oxide minerals. The difference in density results in an easy separation and segregation of one or the other component during sample travel and recovery. There may also be a marked difference in the particle size between the gangue and ore minerals produced during rotary or percussion drilling. The drilling may yield a coarser and a finer component in either iron mineral or gangue so a sampling error may result as correct amounts of fine and coarser material may not be recovered. This can result in a considerable change in iron content in the samples obtained through the loss of either coarse or fine material. A loss of fine gangue material, often quartz, is common, which may result in a considerable apparent increase in iron content of the ore. Until modern, high core recovery diamond drill methods for sampling iron ores were developed in the 1950s and 1960s, elaborate and questionable formulas were used to combine the core and sludge samples received to give the ore assay. In past years, sampling of the Lake Superior type ore for open pit mining on the Mesabi Range included percussion drilling using a variety of drill machines such as churn drills and the use of a dry, punch coring method accomplished by driving a nonrotating, hollow bit into the ore to retrieve an unwashed, unsegregated sample. The current method used in exploration or development sampling of natural iron ores or concentrating grade natural iron ore on the Mesabi Range is by diamond drilling using N size, swivel type core barrels and bentonite mud as the drill fluid with the work done by skilled drill crews. This drill system commonly yields a sample with the needed amount and size of core for analysis and testing that has an acceptable accuracy. Even using this system there are interlayered hard and soft ores that may cause severe sampling problems.

Exploration drilling and sampling of compact, massive, nonfriable iron ores is usually done by core drilling. Diamond core drilling, in what may be termed solid ores, is cost effective. In most cases the work is accomplished with a very high core recovery, often between 95 and 100%. The wireline method is extensively used as it can give adequate sample material with excellent sample recovery at a reasonable cost. Surface set diamond bits and modern swivel type core barrels used with standard drill equipment and drilling methods commonly give satisfactory core samples, although the use of bentonite mud as the drilling fluid should be considered as it may improve drilling and sample recovery particularly in fractured zones. Detailed information on core drill equipment including wireline, core barrels, types of bits and advice on their use can be obtained from the drill equipment manufacturers and contract drilling companies.

Some iron mining companies, particularly those working in areas with substantial glacial cover, use a rotary drill to penetrate the glacial drift. This equipment must be of sufficient size and power to effectively drill in the glacial materials. The rotary drill is used to reach the bedrock surface

where casing is set. Bedrock drilling is then done using diamond drill equipment. In bouldery surface materials it is sometimes best to use down-the-hole percussion equipment instead of a rotary drill. Overburden that contains large, hard boulders may be drilled with larger-sized diamond drill holes with casing set in bedrock. The use of bentonite in drilling has largely overcome the difficulties of drilling and setting casing in surface materials.

Drill Hole Surveys

Surveying drill holes should be considered an essential part of an exploration drilling program whenever accurate knowledge of the position of the hole from top to bottom is important to the evaluation of the deposit and to its eventual development. Deviation of drill holes from the planned direction and angle is common in holes that are over a few hundred feet in depth and should be expected. The severity of the vertical and horizontal changes ranges considerably. Deviations of from 5° to over 20° in inclination and up to 20° in horizontal direction have been observed in drill holes less than 245 m (800 ft) deep that were drilled in steeply dipping cherty iron-formation. Thus the change in bottom hole location can be substantial. Deviations in holes drilled in dipping, bedded, cherty iron-formation with alternating harder and softer layers can be remarkably rapid.

In iron ore exploration sufficient magnetite is commonly present to make magnetic borehole survey methods unreliable, so the use of a gyroscopic survey system is recommended. The first use of a gyroscopic system in a small diameter diamond drill hole was done at the Atlantic City taconite mine near Lander, WY, in 1966. Drilling was performed to obtain detailed information to permit the development of final open pit mine plans. This required that stripping be carried to the ultimate pit limit during mining. A substantial deviation in the inclination of drill holes was observed so horizontal deviation was suspected. Sperry Sun was encouraged to complete construction of a partly designed, small hole gyroscopic survey system that could enter a BX diameter hole. The resulting survey showed a substantial horizontal deviation in the exploration drill holes, requiring a relocation of the stripping limits. Mining has since shown that the gyroscopic survey results were accurate.

Gyroscopic drill hole surveys can be made on a contractual basis with well service companies. These surveys produce records that show the hole inclination and direction with a relatively small possible error. Well service company personnel are also available to assist with cost estimates and to assist in planning a drill hole survey program.

SAMPLING AND GRADES

Sampling is an important and difficult part of the exploration and evaluation of an iron ore deposit. Iron ore bodies of potential economic value commonly contain from a few million to several hundred million tons of ore material. The gathering of small amounts of material from properly distributed points in an ore body so the composite results of their analysis and research testing accurately represent, in a consistent way, the whole body and its variability can be a formidable undertaking. The accuracy and thoroughness of the sampling methods should be under constant review, with deliberate checks and evaluations to prevent gathering inaccurate samples that can lead to erroneous conclusions.

Iron ores can be conveniently divided into two major types: (1) natural iron ores, which include both merchantable ores and crude ore materials that can be beneficiated by simple methods, and (2) concentrating grade ores that require

fine grinding before processing to yield an ore grade product. Each general type has its particular sampling methods and problems.

The sampling of a natural iron ore deposit must determine the distribution of various ore grade materials within the ore body in regard to physical and chemical characteristics and, where needed, the suitability and yield amounts of shipping product obtained from the nonmerchantable materials that require beneficiation. The usual and customary chemical requirements determined by sampling include analysis for Fe, SiO₂, Al₂O₃, P, Mn, CaO, MgO, S, loss on ignition, and moisture. In ores where other elements are commonly present, analysis for special elements may be required. As an example, an analysis for TiO₂ is required for titaniferous magnetite ores. Ores with a high iron content, low scavenger, slag-forming constituents (SiO₂, Al₂O₃, CaO and MgO) and very low amounts of deleterious elements are preferred. While scavenger, slag-forming constituents are needed in the blast furnace, it is preferable that these be added at the furnace in controlled additional amounts as required. The slag volume desired varies with blast furnace practice and the nature and amounts of elements such as phosphorus and sulfur that need to be removed in the slag. Most ores do not contain the desired ratio of material used for slag formation so low amounts of these impurities permit easy preparation of the furnace burden.

A considerable list of elements is considered deleterious. The more common, unwanted elements in iron ores include phosphorus, sulfur, and titanium, with a less common to uncommon occurrence of vanadium, copper, zinc, chromium, nickel, arsenic, lead, and tin. Phosphorus is common to most iron ore in amounts that may range from very low (about 0.005%) to very high (over 1% P). Because of the importance of phosphorus in steelmaking, iron ores have long been classified on their phosphorus content, as Bessemer—not over 0.045%; low-phos non-Bessemer between 0.045 and 0.180% P; and high-phos non-Bessemer over 0.180% P. There is a price differential that recognizes the phosphorus grades. With a decline in the production of merchantable ores and the major tonnage production of beneficiated ore and pellets from concentrating grade ores having a low phosphorus content, there has been a lessening of concern with the phosphorus content of ores in steelmaking practice in the United States. There are still major concerns with the phosphorus content in natural ores moving in international trade, as there seems to be a very limited market for high grade iron ore that contains more than 0.07% phosphorus. In the Lake Superior region, iron ore that contains over 2% manganese is classed as manganiferous ore with a premium paid for ore containing in excess of 5% Mn. There often is some small price recognition for ore with a manganese content below 5%. The iron ore industry also, in past years, has shipped a small tonnage of ore classed as siliceous ore. This ore should be considered a special situation ore and requires a special sales arrangement in order to be recognized as ore in the sampling and evaluation of an iron ore deposit. This fact is apparent from the analysis of the 1971 Tilden silica grade ore, which was 38.96% Fe and 40.41% SiO₂.

The physical characteristics of natural ore that influence the evaluation of these ores primarily concern the relative quantities of coarse, plus about 6.35 mm (0.25 in.), and fines. This distinction is important as it determines the amount of the shipping product that can be charged directly into a blast furnace after the ore has been crushed and sized in comparison with the ore that will require agglomeration by sintering or pelletizing before charging. The determination of

the physical parameters is often poorly shown by samples obtained by drilling, so trenches, test pits, adits, or shafts are dug to obtain an adequate sample for crushing and screening tests.

The primary sampling of a natural ore deposit during exploration is commonly done by drilling. Drilling iron ore deposits that can be mined by open pit is done either in a grid pattern or along section lines, so cross sections can be prepared to show the distribution of grades of ore. Samples are commonly taken on 1.5 or 3 m (5 or 10 ft) intervals with a recognition in sampling of visible changes in the physical appearance of the ore and of geological boundaries. If core drilling is done, the core and/or sample is split, retaining one half for future study and reference. Samples, properly identified as to drill hole and footage, are sent for chemical analysis. Materials that are not of ore grade are sent for laboratory tests to determine suitability for beneficiation and the analysis of concentrated product. The laboratory personnel commonly determine the proper concentration tests to be used. The analyses and/or test results when received are plotted on maps and sections, and are identified as to ore grades and types for use in ore tonnage determinations and for mine planning. At many mines the drill and analysis results are entered into a computerized data system.

Sampling of concentrating grade, *hard rock* type ores, such as magnetite taconite, jaspilite, OXIBIF, and contact replacement ore, is commonly done by core drilling using diamond bits. In deposits such as Mesabi Range magnetite taconite having large lateral extent, the drilling is often done as a phased program with a relatively wide spacing of drill holes in the initial phase to quickly determine the ore occurrence and the size of the deposit with progressively closer drill hole and section spacing as the exploration drilling passes into development drilling. Often there is no marked demarcation between exploration work and development work in the sampling of an ore body, although there may be a modification of drill procedure. Splitting of the drill core is strongly recommended during the preliminary exploration stage, with one half of the core retained for later study during the exploration, development, and mining stages. After a competent general knowledge of the ore body has been obtained, and when the purpose of continued drilling is to give adequate knowledge of ore grade distribution for detailed mine planning and ore grading for mine production, the core size may be reduced with all ore grade core sent for analysis and testing. Drill core recovered should be logged by a competent geologist, geological boundaries marked, and sample units determined. The core footage included in a single sample for analysis or for laboratory tests should be varied as needed to show variations in the ore occurrence so maximum use can be made of the sample data in mine and production planning.

Bulk Sampling

Bulk sampling is an essential part of exploration and evaluation of iron ores. Large samples are required to check the accuracy of the drill samples and to obtain the needed information on the crushing and grinding characteristics of the ore as well as for use in detailed and large-scale metallurgical tests. In natural ores, bulk samples give information regarding the nature and quantities of various sized ore products that can be shipped. Herkenhoff (1968) in a discussion of the need for large samples of natural iron ores points out the importance of information on how the ore fractures in blasting and breaks into fine sizes during mining, crushing, and in all subsequent handling steps, such as trucking, stock-

piling, ship loading, and ship unloading. He states, "On the Mesabi Range where jig and heavy-media ores occur, it is always critically important to determine what percent weights would be in the 64 mm (2.5 in.) plus 6.35 mm (0.25 in.), minus 6.35 mm (0.25 in.) plus 0.21 mm (65 mesh), and minus 0.21 mm (65 mesh) fractions because these splits directly affect capacity required for the respective heavy-media separation cyclone (or jig) and spiral plants which are to work in concert when processing the run-of-mine crude. Because HMS is more efficient than other processes, it is advantageous to keep as much material as possible in that size range. So the problem in sampling ores is to obtain material at least 102 mm (4 in.) in top size and to try to duplicate a typical plant feed structure."

"On the other hand, if the ore is found to require complete crushing and grinding to, say, minus 0.21 mm (65 mesh) for beneficiation by flotation, spirals, etc., there is not much use in striving to obtain material coarser than diamond drill core size . . ." As Herkenhoff indicates, even in iron ore districts as well known as the Mesabi Range, bulk samples of some ores may be required but for other ore bodies high quality drill samples may be sufficient to determine the beneficiation characteristics. In areas where the accumulated knowledge regarding the expected natural ore characteristics is not well known, bulk sampling may be required for all ore deposits.

Bulk sampling is recommended for concentrating grade iron ore deposits that require fine grinding to attain iron mineral liberation before concentration. Accurate data are needed concerning the various types and/or grades of ore present and all aspects of the mining and processing of the ore materials to the final agglomerated product. These data should include information on drilling, blasting, fragmentation, crushing, grinding, concentration, and agglomeration for use in mine pit design, mine production schedules and to permit the development of a flow pattern for the correct correlation of product mix and feed rates to each successive process unit. Needed information includes ore type classification, iron content, mineralogy, liberation characteristics, feed size distribution, grindability indices for each ore type, and the optimum feed rate relationships for each step of processing to final product. It is critically important that specific information be available concerning the various types of ore that must be blended to obtain the normal mill feed grade. This commonly requires the selection of bulk samples from each ore type so a blended mill feed can be prepared and tested in the laboratory and pilot plant. Much valuable data will be available as a result of analysis and bench scale testing of drill core samples, but reliable information for mine and plant design can only be adequately known from the mining and pilot scale processing of the various ore materials. As an example, before the Atlantic City taconite mine and mill were built, two 1360-t (1500-st) bulk samples were obtained from a 222-m (728-ft) long adit. The two samples represented major types of taconite ore that were recognized during test drilling. The bulk samples were shipped from Wyoming to the Pilotac plant located at Mountain Iron, MN, for plant tests. The bulk samples confirmed the drill results and laboratory tests and furnished needed information for final design plans (Cohlmeyer, et al., 1962). Whether bulk samples are sent to an existing plant for testing or a pilot plant is built at the ore deposit depends on the availability of a plant where the bulk sample can be sent and other factors. When the iron ore body at the Jeannine Lake deposit, Quebec, was tested, a pilot plant was erected on site.

Bulk samples can be obtained in a number of ways, such as from the surface area by test pits, trenches, or small open

cut mine pits or from underground openings such as adits, shafts, tunnels, and drifts. In a number of iron ore deposits there may be a marked zone of oxidation and leaching at or near the surface, so surface samples may not be representative of the main body of ore. The validity of the bulk sample in regard to the purpose for which it is taken and the expected ore type is of paramount importance. The sample must be representative of the desired material. Because of the importance of the large-scale testing to several aspects of mine and plant design, there is small latitude for compromise or error. There often is a temptation to use easily available surface material even though it is somewhat altered. This approach should be firmly rejected. The ability to examine and to test bulk sample material from each ore type present in an iron deposit may be essential to the development of a final mine plan, plant flowsheet, and mill design. The several ore type bulk samples can be blended to a number of simulated mill feeds for process and flowsheet development planning.

EVALUATION OF IRON ORE DEPOSITS

Iron ore deposits are evaluated to appraise their worth for possible sale, or, most often, to determine the potential for a profitable mine operation. The results of an evaluation are commonly reported in monetary terms of the present worth of the property or as the cost and profitability per ton of shipped product. Evaluation methods used for an iron ore body are generally similar to the approach used for base or precious metal or industrial mineral deposits with the special recognition of factors characteristic of iron ore deposits and the iron ore industry. A characteristic of the iron ore industry having a major impact is the shipping of a product that is an unrefined, relatively low value, bulk material that moves in large amounts to rather restricted and specific market sites.

The evaluation of a property made to determine its value or profitability is often a team effort involving geologists, engineers, process metallurgists, and economists. In some cases, the evaluation should include the likely users of iron ore at the steel plant, as the profitability determination of an iron ore may reach to the eventual cost of hot iron metal made from the ore. Each team member brings special talents to the study. The geologist has the best knowledge of the physical occurrence and characteristics of the ore deposit; the engineers, of mine and production planning; process metallurgists, of plant requirements and design; iron makers, of feasibility aspects of metal production. The entire group working with economists links all elements into costs and potential profit. Fortunately or otherwise, the value and potential profitability fluctuates with time. An evaluation does not have a fixed validity even though it may be accurate when made. Also, each deposit is unique, so the evaluation of one ore body cannot be safely extrapolated to apply to its neighbor. This was well stated by Pardee (1957, p. 454): "All evidence available is considered for each mine and in this way each mine is treated as an individual problem." This individuality does not exclude the use of accumulated wisdom or the use of comparable information in preparing the evaluation, but requires specific treatment of each factor with regard to the deposit being evaluated.

An important question to consider during the exploration and development of an iron ore deposit is: when should an evaluation be made? There are conflicting ideas regarding this. The difference in opinion is, in part, a result of the perceived viability of a project. Some ore bodies are very obviously viable so the question to be answered is not whether

to continue the project but how profitable will it become. In other cases there may be serious questions regarding viability. Often a series of evaluations may be advisable, which may include: (1) a limited pre-exploration evaluation, (2) a limited mid-exploration evaluation, and (3) a post-exploration and predevelopment, full-scale feasibility evaluation. The pre-exploration evaluation is usually a rather limited effort as geological evidence may be sketchy or essentially lacking. The main purpose of this evaluation is to assess the likely geological conditions and the nongeological factors using a hoped-for, assumed ore body so an eventual discovery should be viable if it meets the expected ore body characteristics. The second, mid-exploration evaluation, would be made after ore has been found, the general geological aspects of the body known, with some analysis and research test information available. This evaluation would permit site specific, somewhat generalized data to be used with a reasonable knowledge of the ore types and grades, processing required, and the likely product analysis and characteristics. The post-exploration and predevelopment feasibility evaluation would be made when adequate information is available for a complete evaluation of the profitability potential.

The evaluation of an iron ore deposit involves a considerable range of factors from the physical, chemical, and geological to the political, governmental, social, and environmental. Ohle (1972) lists 22 factors, of which 9 are termed geological and 13 nongeological (see Table 2).

The list of factors in Table 2 is very condensed, as there are often a number of cogent aspects to each that should be included in the study. The amount and precision of the information required to permit an adequate evaluation will vary with the stage in exploration or development at which the evaluation is being made. An evaluation report should indicate its purpose and its time relationship in the exploration program as there may be a considerable range in data availability and in its accuracy. The validity of the conclusions may also vary with the quality of the evaluation data. The report should include a clear statement of information limitations. The pre-exploration evaluation report is often made using optimistic projections as a pessimistic outlook would launch few exploration projects.

Since the market for iron ore is at an iron and steelmaking facility, the availability of a market may be a critical factor in the evaluation of an iron ore body. A deposit that is viable in one location may be of little or no value or only be potentially viable at another. Property or plant ownership and/or long-term contract relationships of a steel plant to an established source of iron ore may materially influence the value of a new potential source of iron ore. A market survey and long-range study of iron ore requirements at all potentially available market sites may be essential to many iron ore exploration and development projects.

The physical facts needed include an estimate of capital costs, developmental requirements, product quality, etc. Ohle (1972) presents the possible evaluation relationships in four case studies. The four cases used by Ohle include one high grade, merchantable ore body, two magnetite taconite deposits, and a deposit of oxidized taconite (roast ore), which in this section is classified as OXIBIF ore. The same basic questions regarding the physical characteristics of a possible mine development such as the ore characteristics and grade, type of mine development, ore processing required, grade of the shipping product, and the estimated capital cost need to be answered for each ore type. The wide range in the physical aspects of the four cases is well shown by the estimated range in capital cost, from $\$21 \times 10^6$ to $\$240 \times 10^6$.

Table 2. Important Factors in the Evaluation of Iron Ore Deposits from Ohle (1972).

- A. Geological Factors
1. Type and Grade: Direct shipping, wash, heavy media, taconite, etc.; Rice ratio,* impurities, and associated elements.
 2. Tonnage: Crude and product, effect on capital cost and recuperation schedules; weight recovery.
 3. Grain-Size: Grind size, texture, liberation of ore minerals, elimination of impurities.
 4. Grindability: kW - hr per ton to reduce the ore to concentrating and agglomerating sizes.
 5. Mineralogy: Magnetite, hematite, goethite, silicate, or carbonate. Impurity mineralogy—effect on the ability to separate the impurities in processing.
 6. Distribution of ore types: Grades, textures, mineralogies—can selective mining be done?
 7. Depth and nature of overburden: Sand and gravel, or rock. Open pit vs. underground mining.
 8. Shape and attitude of the ore body: Tons per vertical foot. Effect on stripping ratio.
 9. Location: Topographic effects, climate.
- B. Nongeologic Factors
1. Market and Price: Individual company variations in requirements and locations of furnaces.
 2. Politics and general business climate.
 3. Transportation cost.
 4. Labor and housing: Availability and cost.
 5. Construction cost.
 6. Power: Availability and cost: fuel.
 7. Water supply.
 8. Taxes.
 9. Royalty rate.
 10. Inflation factors.
 11. Tailings disposal.
 12. Environmental factors: Ecology.
 13. Financing.

$$* \text{ Rice ratio} = \frac{\text{Fe}}{\text{SiO}_2 + \text{Al}_2\text{O}_3}$$

When the results of a study of the physical facts concerning a deposit are available, the evaluation can move to an economic analysis that will present the cost and profit aspects of the evaluation. Table 3 gives a listing of the economic information needed to show the total cost of the product, after-tax profit, cash flow, payback time, and percent return on investment.

The summary economic analysis from Table 3 can easily be modified to suit any ore body and possible market. A determination of the market value of iron ore may be a problem as the price of iron ore is only published on a regular basis for Lake Erie ports. The Lake Erie price is regularly quoted in the market section of *Engineering and Mining Journal* and in some other journals such as *Skilling's Mining Review*. Much iron ore is sold under long-term contracts at negotiated prices. The ore price may not be publicly available. Spot iron ore purchases may also be negotiated so it may be difficult to document a current iron ore value based on actual ore sales except as adjusted to the Lake Erie price.

The evaluation of an iron ore deposit requires a special knowledge of the iron ore industry that often extends far beyond the locality of the ore occurrence. Today iron ore is a major commodity in international trade. Super-large bulk cargo vessels have reduced ocean transport costs to a level that permits a competitive relationship for a number of iron ore sources to be global in extent. This world view of the iron ore trade complicates the evaluation of any deposit as the physical facts of ore occurrence become a smaller part of the cost/profit analysis. The extension of the potential profitability of an ore to include its use at the steel plant further extends an in-depth study from the ore in place through the complete process to iron as metal.

2.6 Coal

WILLARD E. WARD, II

DEFINITION

Coal is a physically and chemically complex substance that has been defined in different ways over the years. Currently, the most widely accepted definition is that adopted by the American Society for Testing & Materials (ASTM) which is as follows:

“Coal is a readily combustible rock containing more than 50 percent by weight and more than 70 percent by volume of carbonaceous material including inherent moisture, formed from compaction and induration of variously altered plant remains similar to those in peat. Differences in the kinds of plant materials (type), in degree of metamorphism (rank), and in the range of impurity (grade) are characteristic of coal and are used in classification (ASTM, 1970, p. 70).”

CLASSIFICATION

Because of the complexity of its physical and chemical properties and its varied uses, the classification of coal is not a simple task. Many classification schemes for coal have been proposed over the years using a variety of parameters as criteria. Of the various approaches to classification, rank is one of the more important. Rank is a measure of a coal's thermal maturity, that is, its position in the coalification series. Coalification refers to the progressive transformation of peat through lignite, subbituminous, bituminous, and anthracite. The standard rank system used in North America is the ASTM system (Table 1). It is based primarily on fixed carbon, volatile matter, and calorific value and utilizes familiar rank terms such as lignite, bituminous, and anthracite. In the ASTM system, these terms have specific meaning with regard to the aforementioned parameters, but may conflict with meanings given to the same terms in another country's classification system.

Coals are also classified by type into two broad categories: (1) sapropelic or nonbanded coal, and (2) humic or banded coal. Nonbanded coals exhibit little or no apparent stratification, are frequently granular in texture, tend toward homogeneity, and are allochthonous in origin. Examples of nonbanded coals are boghead coal, composed primarily of algal remains, and cannel coal, which consists largely of spores.

Banded coals, by contrast, are composed of a series of layers which are parallel to the bedding and which can be distinguished on the basis of macroscopic characteristics such as luster, hardness, etc. These bands are known as lithotypes and are composed, in turn, of macerals, which are the microscopically identifiable components of coal. Macerals are defined on the basis of color, morphology, association, and fluorescence. Maceral analysis plays an important role in the coal evaluation process and yields valuable information concerning the nature of the paleoenvironment in which the coal was formed, the degree of thermal maturity of the coal (rank), and its suitability for particular uses.

Of the two types, banded coals are by far the more abundant and constitute the majority of the world's coal resources.

ORIGIN OF COAL

Coal is formed by the accumulation and preservation of organic material (primarily from plants) in swamp, marsh,

or bog environments. This plant material is altered into peat by complex biochemical processes that are still poorly understood. Peat accumulates very slowly relative to the human lifespan. Accumulation rates in Florida and the Mississippi Delta are from 0.5 to 1 mm/a, whereas in Borneo rates of up to 4 mm/a have been recorded. Generally, accumulation rates are higher in tropical climates than in temperate to cool climates although the higher growth rates are partially offset by slower decomposition rates in cooler climates. Peat can accumulate whenever accumulation rates are higher than the rate of decomposition. Most ancient coals probably originated in temperate to tropical climates (Bustin, et al., 1983).

As geological conditions change in peat-forming areas, the peat deposits may become buried by subsequent influxes of sediment. Sedimentation may continue for very long periods of time and, when coupled with the subsidence of the depositional basin, can result in the burial of the peat deposit under thousands of meters (feet) of sediment. Heat and pressure generated by the weight of the sedimentary column, in addition to biochemical and geochemical processes, cause the coal to increase in rank. The level of coalification attained is primarily a product of temperature and length of time of heating. Because in most stratigraphic sequences temperature increases uniformly with depth, the more deeply buried coals are generally of higher rank. Generally, as rank increases, porosity, volume, volatile constituents, and water decrease, while fixed carbon, density, heating value, and reflectance increase.

The main byproducts of coalification are methane, carbon dioxide, and water. Water is lost early in the coalification process and the ratio of methane to carbon dioxide increases with rank (Bustin, 1983). Large volumes of methane may be generated during coalification and can be produced and marketed either in conjunction with underground mining or as an independent venture. In fact, in the Black Warrior Basin of Alabama, 25% of natural gas production on an annual basis currently comes from degasification of deeply buried coal beds.

DEPOSITIONAL ENVIRONMENTS

The thickness, lateral distribution, composition, and quality of a coal bed are determined to a great extent by the depositional environment. Moreover, Horne, et al. (1978) found that the aforementioned characteristics were determined by the depositional environments that preceded, were coeval with, and that immediately followed deposition of the peat. The preceding environment shapes the topography on which the peat is deposited and therefore affects the thickness and lateral extent of the deposit. Contemporaneous environments affect seam continuity and composition whereas later environments may affect the peat by partial or complete removal of the deposit by erosion or, if brackish or marine waters are introduced, alteration of peat chemistry and therefore of coal quality.

Coal-forming environments can be divided into two broad categories: (1) paralic, which refers to coastal or near-coastal marine settings, and (2) limnic, which refers to coals formed inland, usually in intermontane regions and under freshwater conditions. Generally, limnic coals are characterized by thick

Table 1. ASTM Classification of Coals by Rank[†]

Class	Group	Fixed Carbon Limits, % Dry, Mineral- Matter-Free Basis		Volatile Matter Limits, % Dry, Mineral- Matter-Free Basis		Calorific Value Limits, Btu per lb (Moist, [‡] Mineral-Matter-Free Basis)		Agglomerating Character
		Equal or Greater Than	Less Than	Greater Than	Equal or Less Than	Equal or Greater Than	Less Than	
I. Anthracitic	1) Meta-anthracite	98	—	—	2	—	—	Nonagglomerating
	2) Anthracite	92	98	2	8	—	—	
	3) Semianthracite*	86	92	8	14	—	—	
II. Bituminous	1) Low volatile bituminous coal	78	86	14	22	—	—	Commonly agglomerating [§]
	2) Medium volatile bituminous coal	69	78	22	31	—	—	
	3) High volatile A bituminous coal	—	69	31	—	14,000 [†]	—	
	4) High volatile B bituminous coal	—	—	—	—	13,000 [†]	14,000	Agglomerating
	5) High volatile C bituminous coal	—	—	—	—	11,500	13,000	
III. Subbituminous						10,500	11,500	
	1) Subbituminous A coal	—	—	—	—	10,500	11,500	Nonagglomerating
	2) Subbituminous B coal	—	—	—	—	9,500	10,500	
	3) Subbituminous C coal	—	—	—	—	8,300	9,500	
IV. Lignitic	1) Lignite A	—	—	—	—	6,300	8,300	Nonagglomerating
	2) Lignite B	—	—	—	—	—	6,300	

[†] Source: ASTM *Annual Book of Standards*, 1981. Metric equivalent: lb × 0.453 592 4 = kg.

* This classification does not include a few coals, principally nonbanded varieties, which have unusual physical and chemical properties and which come within the limits of fixed carbon or calorific value of the high-volatile bituminous and subbituminous ranks. All of these coals either contain less than 48% dry, mineral-matter-free fixed carbon or have more than 15,500 moist, mineral-matter-free Btu's per lb.

[‡] Moist refers to coal containing its natural inherent moisture but not including visible water on the surface of the coal.

[§] If agglomerating, classify in low-volatile group of the bituminous class.

^{||} Coals having 69% or more fixed carbon on the dry, mineral-matter-free basis shall be classified according to fixed carbon, regardless of calorific value.

[¶] It is recognized that there may be nonagglomerating varieties in these groups of the bituminous class, and that there are notable exceptions in high volatile C bituminous group.

beds of limited lateral extent. Although some of the coals in the western United States are limnic in origin, most North American coal deposits appear to have formed in paralic environments.

Paralic environments can occur in back barrier, deltaic, or coastal and interdeltic settings (Bustin, 1983). Back barrier coals develop landward of barrier islands, frequently in abandoned lagoonal basins that are formed between the barrier islands and the mainland. Back barrier coals are typically rather thin, laterally discontinuous deposits that are elongate parallel with depositional strike and that are usually high in sulfur and ash.

Coastal plain coals develop on low, relatively flat, subsiding coasts that have a high water table and little influx of sediment. Some of the more persistent coals in the Appalachians of the eastern United States may have been deposited in coastal plain settings. Modern coastal plain swamps that are active sites of peat accumulation include the Everglades of Florida and the Okefenokee Swamp of Georgia (Bustin, 1983).

Many ancient coals are interpreted to have formed in deltaic systems and thus depositional environments associated with deltas have been the subject of intensive investigation.

The following comments on coal-forming environments in deltaic systems are drawn from Horne, et al. (1978). Depositional modeling can be used to predict large-scale trends in coal deposits on a regional scale and are therefore useful in the initial phases of coal exploration. Further, small-scale variations in coal thickness, quality, and lateral continuity frequently can be predicted, providing data that can be extremely valuable in mine planning and development.

The following illustration (Fig. 1) was derived from a detailed data base developed from the coal-bearing carboniferous-age rocks of eastern Kentucky and southwestern Virginia and from similar environments in contemporary coastal

areas. Fig. 1 illustrates the typical shape and lateral extent of coal deposits which form in the different environments within the deltaic setting.

Coals that form in lower delta plain environments are typically elongate parallel with depositional dip because the only environments suitable for peat accumulation are adjacent to relatively narrow levees on either side of distributary channels. Interdistributary bays occur between the distributary channels and are sites of accumulation of fine-grained bay-fill detrital sediments. Sites of peat accumulation on the lower delta plain are generally restricted to the elongate, relatively narrow areas between the levees and the interdistributary bays. Lower delta plain coals are usually relatively thin and contain splits caused by crevasse splays that breach the poorly developed levees along the distributary channels.

Upper delta plain-fluvial coals also tend to be elongate in the direction of depositional dip although they are not as continuous in that direction as the lower delta plain coals. Deposits typically formed as pod-shaped bodies on flood plains adjacent to coexisting meandering channels and exhibit significant thickness variations over short distances. Also, as in the case with lower delta plain coals, numerous splits can occur near the levees bordering active channels because of splays. Post-deposition shifting of channels can also complicate the sedimentary sequence by eroding the coal deposit and creating "washouts."

In some locales, a transitional zone exists between the lower and upper delta plain environments that exhibits characteristics of both lower and upper delta plain sequences. In the transition zone between the lower and upper delta plains, many of the large interdistributary bays (flood basins) that occur between distributary channels have filled with sediment and provide broad basins in which large coal swamps can develop. These broad, relatively uninterrupted basins provide a favorable environment for the formation of coal deposits that are typically more laterally extensive than those of the

Fig. 1. Depositional model for peat-forming (coal) environments in coastal regions. Upper part of figure is plan view showing sites of peat formation in modern environments; lower part is cross section (AA') showing, in relative terms, thickness and extent of coal beds and their relations to sandstones and shales in different environments (Horne, et al., 1978, reprinted by permission of American Association of Petroleum Geologists).

Fig. 2. Reconstruction of depositional setting immediately after formation of coal X. Diagram is based on data related to lithologic and sediment-thickness variations (Horne, et al., 1978, reprinted by permission of American Association of Petroleum Geologists).

lower and upper delta plain proper. Coals formed in this transitional zone share some characteristics with upper and lower delta plain coals such as splits that develop near levees and post-depositional washouts. Most of the more economically important coal beds in the Appalachian coal region are interpreted to have developed in this transitional zone between the lower and upper delta plains.

From the foregoing brief discussions, it is apparent that, in the initial phases of exploration, a knowledge of the depositional environments that control the shape and configuration of the coal body will enable explorationists to design a drilling program for maximum effectiveness and efficiency in defining the coal deposit. At the lease-tract or mine plan levels of exploration, more detailed drilling and evaluation may be desirable to predict areas of thick and/or high-quality coal.

Depositional environments also partially determine the sulfur content of coal deposits. Sulfur occurs in the form of iron sulfide (predominantly pyrite) in several ways in coal. A finely disseminated form sometimes referred to as framboidal pyrite is the most reactive form of pyrite and the most difficult to remove. It is so finely disseminated throughout the coal that it cannot be removed effectively in float-sink washability tests. Research suggests that framboidal pyrite originates from sulfur produced by microorganisms found in marine to brackish waters, but not in fresh water. It has been shown (Ferm, 1976; Caruccio, et al., 1977) that framboidal pyrite is most strongly associated with coals overlain by roof rocks deposited in marine to brackish-water environments. Exceptions occur when a blanket of sediment (such as a crevasse splay) is introduced early enough to shield the peat deposit from later marine to brackish-water transgressions. It follows that coals which formed in back barrier to lower delta plain environments are more likely to be overlain by sediments deposited by marine to brackish water and hence will be more likely to contain higher amounts of framboidal pyrite.

Coals that formed in transitional lower delta plain environments are subject to a mix of fresh and brackish to marine water influences and hence are highly variable in their sulfur content. Generally, however, transitional lower delta plain coals are considered to be lower in framboidal pyrite than coals deposited in lower delta plain and back barrier settings. This trend is thought to continue for coals formed higher in the delta plain in fluvial-upper delta plain settings where marine influence is uncommon. These coals are generally considered to be lower in finely disseminated

pyritic sulfur than coals formed in other delta plain depositional settings. An understanding of the depositional setting in which a coal bed formed can therefore be used to predict the amount and type of sulfur present and to guide the exploration for low-sulfur coals in areas where sulfur contents are usually high.

Investigations by Caruccio, et al. (1977) and Horne, et al. (1976), serve as examples to illustrate the potential usefulness to mine developers of understanding the depositional history of a coal bed. Using a data base of 450 core holes in a 518-km² (200-sq-mile area) located in the Appalachian coal region of the eastern United States, the investigators interpreted the target coal bed to have been deposited in a lower delta plain setting. Typically, coals interpreted as lower delta plain coals, where overlain by brackish to marine rocks, have sulfur contents of greater than 2% with 75% or more of the sulfur occurring in the form of framboidal pyrite (Caruccio, et al., 1977). Where deposits interpreted as freshwater splays were emplaced over the peat surface prior to the deposition of the marine rocks, the peat apparently was shielded from the sulfur-reducing bacteria, causing the sulfur content in the peat to remain low (Horne, et al., 1976).

Figs. 2 and 3 summarize the investigative results of Horne (1978). Fig. 2 is an interpretation of the depositional environments after deposition of a coal bed. The data suggest that the levees of a distributary channel in the southwestern part of the area were breached and splay deposits encroached to the north and east over the coal and into the marine-influenced interdistributary bay. Fig. 3 shows the distribution of disseminated sulfur in a target bed. A comparison of Figs. 2 and 3 illustrates the expected association between areas where the coal is overlain by marine beds (the eastern part of Fig. 2) and higher sulfur concentrations. In the western and southern parts of the diagrams where the wedge of nonmarine splay deposits covered the coal, sulfur contents are correspondingly lower.

The relationships shown in these diagrams between disseminated sulfur content and specific depositional environments suggest that exploration drilling programs at the lease-tract level should be devised to gain an understanding of the depositional setting of a coal deposit and to define such depositional features as might cause significant variation in the physical or chemical characteristics of the coal.

STRUCTURAL FEATURES AND THEIR EFFECTS ON COAL DEPOSITS

Structural features are those features provided by post-depositional deformation or displacement of the rocks. Such

Fig. 3. Distribution of sulfur in coal X that cannot be removed in 1.50-density sink fraction of washability tests (Horne, et al., 1978, reprinted by permission of American Association of Petroleum Geologists).

Fig. 4. Simplified cross section of coal-bearing sequence in the Appalachian coal region of the Eastern US where rocks have been gently folded into anticline (upfold) at A and syncline (downfold) at B (Simon and Hopkins, 1973).

features can form concurrently with, or shortly after, deposition of the sediment, such as slumps or differential compaction of soft sediments having different densities. These soft-sediment structures can and do sometimes affect the continuity of coal deposits. More commonly, however, it is structural features such as folds and faults that formed later in the history of the rocks as a result of tectonic forces that determine the present attitudes of the coal beds.

Inclined or Folded Strata

Rock sequences deform plastically under conditions of high temperature and confining pressure and hence may be tilted or folded into a series of subparallel to parallel upwarps and downwarps termed anticlines and synclines, respectively (Fig. 4). Folding may be so intense as to lift the strata to the vertical or even to an overturned position. All uplifted strata are more susceptible to subaerial erosion with areas of maximum uplift having the greatest degree of susceptibility. Therefore anticlinal crests are often severely denuded, creating a breached structure and interrupting the areal continuity of any coal beds. The tilting and folding of strata containing coal beds therefore complicates efforts toward correlation of beds from area to area and also imposes constraints on mining operations in areas of intense structural deformation. In most cases the overburden increases more rapidly away from the outcrop in downward pitching coal

Fig. 5. Normal fault showing displacement and direction of relative movement across fault plane. Hanging wall is downthrown relative to footwall. AB is vertical displacement (modified from Simon and Hopkins, 1973).

Fig. 6. Reverse fault showing displacement and direction of relative movement across fault plane. Hanging wall is upthrown relative to footwall. AB is vertical displacement (modified from Simon and Hopkins, 1973).

beds than in flat-lying deposits, reducing the amount of coal that is economically recoverable.

Faults

A fault is a fracture or fracture zone along which displacement has occurred on one side of the fracture relative to the other. Faults are important considerations in coal exploration and mining and, depending on local conditions, can render an otherwise attractive area unsuitable for mining.

There are several types of faults defined by the direction of relative motion across the fault plane. The two types of faults most commonly encountered in coal exploration are normal faults and reverse faults. Normal faults occur where the block above the fault plane (termed the hanging wall) moves down relative to the lower block (the footwall) (Fig. 5). The effect of drilling through a normal fault is that of an apparent shortening of the rock section by the elimination of strata from the column of rock penetrated by the drill. This can be illustrated by visualizing vertical boreholes that penetrate the fault plane on the front panel of Fig. 5. The point where the wellbore enters the footwall is stratigraphically lower than the corresponding point on the hanging wall by an amount equal to the vertical displacement of the fault (AB).

In the case of a reverse fault, the hanging wall moves up relative to the footwall, and repeated sections of strata are encountered (Fig. 6). Vertical displacement is represented by line AB and, once again, each borehole allows a different interpretation of the nature and position of the target coal bed. Indeed, if the middle borehole was the only source of data, an observer might conclude that two coal beds were present if the intervening strata were not carefully evaluated. These examples emphasize the need for a carefully planned drilling program, especially in areas where existing data indicate the presence of faulting. Where faults are known to occur, the drilling program must be designed to yield sufficient data to allow adequate mapping of the type and extent of faulting present as well as the amounts of displacement so that the effects on the coal beds can be accurately determined.

Joints and Cleats

Joints are fractures in a rock mass across which no displacement has occurred. Joints are commonly planar, occur in groups of subparallel to parallel fractures called sets, and may extend, both vertically and laterally, for distances from

as little as a few millimeters (inches) up to many tens of meters (feet) or more. Where jointing is prevalent, it can be a factor in mine planning because it represents existing planes of weakness in the overburden along which the rock will preferentially break during mining. Surface mine highwalls are therefore sometimes planned to parallel the orientation of dominant joint trends and hence take advantage of these natural fracture systems to facilitate blasting and overburden removal.

Cleats are naturally occurring fractures in coal beds (primarily in bituminous coals) that are morphologically analogous to jointing in rocks. Cleats typically occur in two mutually perpendicular sets. Fractures of the dominant set are called face cleats. Face cleats are penetrative, closely spaced fractures that serve as primary conduits for fluids such as methane gas, which is a byproduct of coalification, and ground water. Butt cleats form the complementary, less dominant cleat set and are typically irregular, nonpenetrative fractures that stop against a face cleat, occur over a broader range of orientations, and serve, to a lesser extent, as conduits for fluids. Because of their permeability, cleats in general, and especially face cleats, are often sites of mineralization and deposits of minerals such as pyrite, calcite, and others.

Cleat orientations can be important in mine planning for much the same reasons as joints, that is, they represent natural planes of directional weakness which can facilitate the cutting and loading of an exposed coal bed in a surface mine. Although probably of lesser importance generally than jointing in rocks, cleat orientations have determined, in certain cases, mine layout and the direction of mining.

Clastic and Igneous Intrusions

Perhaps of lesser importance in most locales than the previously discussed structural features is the intrusion of either clastic (sedimentary) material or igneous masses into a sequence of coal-bearing rocks. These intrusions may parallel bedding planes or cut across bedding. In the former case, the features are called sills, in the latter, dikes. These structures can range in thickness from a fraction of a millimeter (inch) up to many tens of meters (feet) and, in certain mining locales, can present significant problems. In the case of a clastic intrusion, the intruded material is waste material and must be separated and removed from the coal but does not alter the physical characteristics of the coal. In an igneous intrusion, the coal in the immediate vicinity of the intrusion is thermally altered. The alteration can result in an increase in rank or even the coking of immediately adjacent coal. An added problem with igneous intrusions is that the igneous rocks are much harder than coal and the associated sedimentary rocks, thereby increasing the difficulty of mining in these areas.

EVALUATION OF COAL DEPOSITS

Determination of the Amount of Coal in Place

Once the decision has been made to proceed with a detailed evaluation of the coal deposits on a particular tract with the purpose of opening a surface mine, a data base must be generated at a level of detail sufficient to characterize the coal and overburden. A number of geological or geophysical techniques can be used to provide data. In areas where a blanket of unconsolidated material was deposited on the erosional upper surface of the underlying bedrock, seismic refraction, seismic reflection, or, in some cases, gravity surveys can reveal the configuration of the bedrock surface. Also, faults with vertical displacements no smaller than 6.1 m (20 ft), or under ideal conditions 4.6 m (15 ft), can be identified

using seismic techniques (Daly, et al., 1976). In the event that igneous intrusives are present, gravity or magnetic techniques can be used to assist in definition of the igneous-sedimentary boundary.

All of the foregoing techniques can, under certain conditions, supply useful data to the coal explorationist but, as general exploration tools, they lack the resolving power for widespread exploration in the coal industry. The carefully planned drilling program remains the primary exploration technique in the coal industry and provides the bulk of the raw data from which coal and overburden characterization maps are made and upon which mining decisions are based.

At the lease tract level, drilling is used primarily to define areas of thick coal and to determine coal quality. These data are then used to calculate measured reserves. Drill-hole density necessary to prove reserves varies with the complexity of the geology and the degree of consistency in coal bed thickness. In areas of structural complexity or where coal bed thickness is highly variable, drill-hole spacing may be as close as one hole every 1.6 ha (4 acres) (Reilly, 1968). Conversely, in geologically undisturbed areas where coal bed thickness is relatively constant, drill holes are sometimes spaced 0.4 km (0.25 mile) or more apart. Local variations in coal-quality parameters (such as sulfur content) constitute another reason to increase drilling density if those parameters are critical in determining the marketability of the coal. Accuracy of the reserve estimate should be within 20% and the drilling program should be geared to produce figures at this level of accuracy (Wier, 1976).

In planning a surface mine, coring of all the exploratory holes probably will not be required. A sufficient number of holes should be cored to allow the geologist to determine the depositional environment of the coal and thereby to make decisions for location of additional test holes and for mine planning. Data from the cored holes will also be useful in determining the type of blasthole equipment and bits as well as types of mining equipment that will be most appropriate. Otherwise, exploratory holes can be drilled by the less expensive air-rotary method. When a coal sample is needed in a particular area, a rotary hole is drilled to establish the elevation of the coal. A second hole is then put down immediately adjacent to the first, still using the rotary bit but stopping the hole just above the position of the coal bed as established by the previous hole. The core barrel and bit is then substituted for the rotary bit and the coal bed is cored.

Systematic sample or core descriptions and recording of coal thicknesses and depths are necessary to insure reliable integration of the data onto the various interpretive maps which are important tools in the evaluation process.

All exploratory holes should have geophysical logs run soon after the drilling is completed. Effective geophysical logging can reduce the number of drill holes required to evaluate a property by maximizing the data obtained from each hole. Geophysical logs serve as a check on written logs and provide a precise record of coal depth and thickness. Geophysical logs of cored holes also provide a means of identifying lithologies in intervals where the core is lost by comparing the logging tools' response to different lithologies in other cored intervals. The basic borehole geophysical suite (calibrated density, gamma, resistivity) can provide the following data: (1) coal thickness and depth; (2) lithologic data; (3) depositional data—nature of contacts and vertical stratigraphic sequences; (4) hydrologic data—aquifers, lost circulation zones, water levels; (5) identification of structural data and stratigraphic sequences; (6) recognition and correlation of specific coal intervals is augmented by their in-

dividual signatures; and (7) recognition of subtle mineralogic changes, such as alteration, that are difficult to discern from cuttings (modified from Crowder, 1986).

More sophisticated geophysical surveys can provide many more types of data such as the coal quality parameters of ash, carbon, volatile matter, heat content, moisture, mineral matter, and rank, at greater cost. Crowder (1986) estimates the cost of a basic geophysical logging suite at 10 to 20% of a total rotary drilling budget with more sophisticated logging suites increasing the cost to as much as 50%. A partial list of geophysical tools and their application to coal exploration is given in Table 2.

Once the data are assembled, the very basic task of correctly identifying and correlating the coal beds throughout the area of interest must be performed. Extra care must be taken in areas where multiple coal beds of varying thickness are present in close stratigraphic proximity to each other. Incorrect identification of the beds can result in a misleading evaluation of the property, which, in turn, can cause severe problems in the mining, preparation, or marketing aspects

of the operation. Geologists commonly use physical characteristics of the overburden, physical and chemical characteristics of the coal bed, distinctive stratigraphic markers or sequences, signatures on geophysical logs, and any other pertinent data to assist in the correct identification and correlation of the coal beds. In more complex areas, additional data may have to be obtained in certain parts of the tract by the drilling of more closely spaced holes before correlations can be made with confidence.

When the coal bed stratigraphy has been worked out, it is useful to construct a series of maps using data obtained from field investigations, drilling, and laboratory work that will depict coal and overburden thickness, overburden to coal ratio, and significant analytical parameters. These maps may be prepared as a series of registered mylar overlays to allow simultaneous viewing of different combinations of data or they may be constructed separately. A structure contour map with the target coal bed as the datum horizon is also an extremely useful method to depict structural or stratigraphic features that affect the topography of the coal bed.

Table 2. Generalized Partial List of Some Drill-Hole Geophysical Measurements for Coal Exploration Applications

Log	Measurement	Applications	Limitations
Natural Gamma	Natural or gross gamma radiation	Lithology, and detection of uranium, potash, etc.	None
Gamma density Four-pi High resolution (HRD) Very High (VHRD) Dual-spaced	Scattered gamma intensity produced by a gamma source	Lithology, bulk density rock mechanics	Need caliper log for quantification. Four-pi is difficult to quantify. HRD-good densities for coal analysis. VHRD-good bed boundary definition-dual density overcomes caliper need somewhat
Resistance Resistivity-focused Resistivity-normal I.P. Spontaneous potential, SP	Complex resistivity Complex resistivity Complex resistivity Complex resistivity Natural earth potentials	Lithology, clay Ash content Sulfide, clay content Lithology, mineral content	Need open, fluid-filled holes. Focused gives best definition because of drill hole fluid resistivity Open, fluid-filled holes, quantitative Open hole
Caliper	Drill hole diameter	Fracture, rock mechanics, change in diameter to correct other logs	Open hole
Temperature	Temperature	Fractures, borehole formation fluid flow	Open, fluid-filled hole
Acoustic velocity	Acoustic pulse, travel time, and disbursement	Porosity, lithology, rock mechanics, fractures	Needs caliper corrections to be quantified
Thermal neutron	Thermal neutron intensity produced by a neutron source	Porosity, lithology, content	Open, fluid-filled hole
Dip log	Formation dip via resistivity measurements	Formation dip, fracture, structure dip, cross bedding	Open hole, lack of sensitivity to low flow rates
Flow meter	Fluid flow in drill hole	Fluid flow determinations	Very costly, slow
Spectral gamma	Natural gamma radiation at different energy levels	Radioactive coals, ash content, lithology	Magnetic tools need open hole
Deviation	Borehole inclination and bearing by magnetic or inertial systems	Borehole inclination and bearing-true thickness, sample location	Very costly, very slow, more development needed for coal applications
Neutron activation	Neutrons resulting from fission of rock after it was activated by strong neutron source	Sulfur content direct mineral in-situ assay	Development continuing
Others	More refined or compensated measurements for above logs	Better bed resolution and analysis

Alternatively, the available data can be entered into a computer data base and appropriate software programs can be utilized to portray stratigraphic, mining, or economic conditions at desired scales.

Coal and overburden thickness maps (termed isopachs) are constructed by plotting the appropriate thickness values on a base map and constructing contour lines (isopachs) representing regularly increasing or decreasing thickness intervals using the plotted values as guides for positioning the contour lines. An example of a coal isopach map is given in Fig. 7. Similar isopach maps can be constructed showing overburden thickness. Isopleth maps can be constructed using the same principle as the isopach maps, but substituting various coal quality parameters for the thickness data (Fig. 8). This type of data presentation would have application where relatively small variations in coal quality would significantly impact the marketability of the coal.

Using the same coal and overburden thickness data, lines representing overburden to coal ratios or "mining ratios" (expressed as 5:1, 10:1, etc.) can be drawn. A ratio of 5:1 means that the line represents the limit at which 0.9 t (1 ton) of coal can be extracted by removing not more than 3.8 m³ (5 cu yd) of overburden. Strictly speaking, this is not a true ratio because it has dimensions of overburden volume per unit weight of extracted coal. The inclusion of these units gives rise to a difference between ratios computed in English units and ratios computed using metric units.

Ratios of thickness values alone cannot be used to deduce mine economics. These values must be converted to cubic meters (cubic yards) of overburden per tonne (ton) of coal to provide data to the analyst in units that can be more readily equated to mining costs. The conversion from feet (or meters) to cubic yards (or cubic meters) per ton (or metric ton) is outlined as follows from Wier (1976):

$$\text{Ratio} = \frac{\text{OB(ft)}}{C(\text{ft}) \times SG \times 0.843}$$

or

$$\text{Ratio} = \frac{\text{OB(ms)}}{C(\text{m}) \times SG}$$

where *OB* is the thickness of overburden, *C* is the thickness of the coal, and *SG* is the specific gravity of coal. Because

of the differences in the units of the English and metric systems, ratios calculated in the metric system are about 0.8 (0.842778) that of the English system. If specific gravity is not known, but the rank of the coal is known, the following specific gravity values are commonly used (Averitt, 1975):

Rank	Specific gravity
Anthracite	1.47
Bituminous	1.32
Subbituminous	1.30
Lignite	1.29

It should be noted, however, that it is important to use correct specific gravity values whenever possible because if the coal contains much mineral matter that has a higher specific gravity than coal, it will skew the results by decreasing the ratio and increasing calculated tonnages per unit area by a possibly significant amount.

Once the overburden lines have been established, the area can then be divided into mining units according to the mining plan and reserves can be calculated. The terms "measured," "indicated," and "inferred" are commonly used to define reserve categories with measured reserves having the highest level of reliability and inferred reserves the lowest. The distance between points of measurement distinguish the different reliability categories. Wood, et al. (1983) uses 0.8, 2.4, and 9.7 km (0.5, 1.5, and 6 miles) as the maximum distance between points of measurement for measured, indicated, and inferred coal, respectively. In mining, however, typical exploration drill-hole spacing is sufficiently close to classify all reserves as measured.

The first reserve determination is for total coal in place. The basic calculations in metric and English units, and using specific gravity for a given coal as determined in the laboratory, are as follows:

$$T = C(\text{m}) \times A(\text{m}^2) \times SG$$

where *SG* is specific gravity, *C* is thickness of coal in meters, and *A* is area in square meters.

In English units:

$$\text{Tons} = C(\text{ft}) \times A(\text{acres}) \times 1359.7 \times SG \quad (\text{Wier, 1976})$$

where *C*, *A*, and *SG* are the same terms as in the metric equation, and 1359.7 is a constant required to establish the correct tonnage factor to use with the English units.

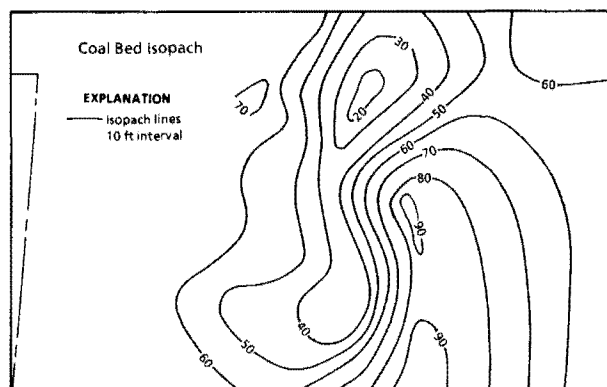

Fig. 7. Isopach map showing variation in thickness of a coal seam (modified from Wier, 1976).

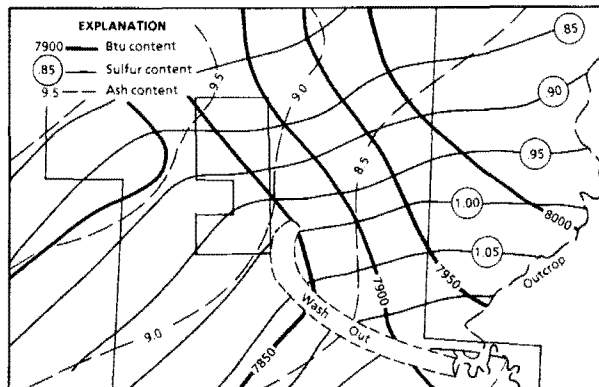

Fig. 8. Isopleth map showing variation in Btu, sulfur, and ash content (modified from Wier, 1976).

If average specific gravity values are used, the following values are frequently used as tonnage factors in a simplified form of the equation.

Rank	Tons of coal per acre per ft of thickness
Anthracite	2000
Bituminous	1800
Subbituminous	1770
Lignite	1750

In the case of bituminous coal the calculation would then be as follows:

$$\text{Tons} = C (\text{ft}) \times A (\text{acres}) \times 1800$$

Resource figures calculated from the preceding equations are estimates only and are not precise, but, with a thorough exploration drilling program, should be accurate to $\pm 10\%$ (Wier, 1976). This figure must then be adjusted downward to account for losses incurred during excavating, handling, processing, and transporting the coal. Anticipating the magnitude of these losses is usually accomplished by drawing on previous mining experience in the area, and in the case of processing or preparation loss, by reviewing washability studies. In some cases, cumulative loss can approach 50% of the total in situ reserve.

Coal Quality

The determination of coal quality is an integral part of the coal exploration process. It is as important as any of the other factors that are used to determine the mining potential of a given tract. Unlike many of the other factors, however, certain coal quality parameters can be changed to meet user specifications by coal cleaning technology and/or by blending with other coals. The following discussion touches on the more commonly used types of analytical data from the viewpoint of the information they convey to the explorationist about the suitability of his product for certain end uses.

Analytical procedures for testing coal have been continuously refined and updated for the past several decades by ASTM (American Society for Testing & Materials). Many major consumers and large coal-mining companies maintain well-equipped laboratories to analyze coal. The consumer does this to check the quality of the coal he purchases, whereas the producer must stay abreast of the quality of the product, especially as the mining operations advance into new territory. Analytical work is sometimes contracted out to independent laboratories either to run the primary analyses or to serve as quality control checks on the mining company's or consumer's results.

The analyses most frequently performed on coal include proximate analysis, calorific value, and sulfur. The proximate analysis consists of the determination of moisture, volatile matter, fixed carbon, and ash. Other types of analyses frequently performed on coal include ultimate analyses, the determination of free swelling index, and determination of trace element content.

Moisture: Moisture occurs naturally in coal beds in a number of different forms and has been determined by many methods. The most common method is through some procedural variant of the measurement of weight loss upon heating. These procedures measure the surface moisture and the inherent moisture, which is that moisture contained in the capillary system of the coal. Moisture contained in the molecular structure of the mineral matter present in coal

(water of hydration) is not accounted for by this type of determination, nor does it include the moisture liberated by the thermal decomposition of organic matter in the coal. The water of hydration is commonly assigned a value of 8% of the ash value and the water of decomposition is not considered significant in most applications. For a more detailed discussion of analytical techniques used in this and other aspects of coal characterization, see Rees (1966). Total or "as-received" moisture, which is the value frequently given in coal analyses, is a combination of surface and inherent moisture and is used for calculating other parameters to the as-received basis. Total or as-received moisture values are critical because coal contracts are often based on as-received calorific values, usually measured in British thermal units per pound of coal, which are obtained by converting dry calorific values to as-received calorific values using total moisture content. Because of the tonnages involved in most contracts, and the fact that most contain penalty clauses for coal that does not meet specifications, even a small error in the moisture content value used to determine as-received calorific value can result in significant financial losses. Moisture content also plays an important role in handling and processing coal. As little as 0.5% surface moisture can cause coal to stick in a chute. Higher moisture contents also cause a decreased coke yield in coke ovens.

Volatile Matter: Volatile matter measurements do not reflect the actual amount of a given substance present in a coal sample but rather are measures of thermal decomposition products that form during the heating of a coal sample under rigidly specified conditions. Examples of volatile materials driven off in the heating process include water, hydrogen, carbon dioxide, carbon monoxide, hydrogen sulfide, chlorine, tar, ammonia, and a variety of organic compounds.

Volatile matter is a parameter used in some coal classification systems. It is used indirectly in the ASTM system for distinguishing between coals of medium volatile bituminous and higher rank. Volatile matter values provide useful information in matching specific coals to appropriate combustion equipment and are also of importance in selecting processes and conditions for the gasification and liquefaction of coal. As a general rule, the best metallurgical grade coking coals contain between 15 and 31% volatile matter and are ranked low- to medium-volatile bituminous in the ASTM system.

Fixed Carbon: Fixed carbon is the carbon that remains in the sample after determination of the volatile matter. The numerical value of fixed carbon is obtained by subtracting the sum of moisture, ash, and volatile matter from 100.

Fixed carbon values are used on a dry, mineral-matter-free basis as boundaries between coals ranked as medium-volatile bituminous and higher in the ASTM system. Because the amount of fixed carbon and ash is an approximation of the amount of coke produced, the fixed carbon value is used to estimate coke yield. It is also used in calculating the efficiencies of combustion equipment.

Ash: Ash is the noncombustible residue that is left when coal is burned. This ash residue derives from two basic sources within the coal bed including: (1) extraneous detrital particles of shale, clay, etc., and secondary mineral material such as calcite, pyrite, and marcasite; and (2) inorganic elements chemically bound in the organic compounds making up the coal. The detritus and secondary minerals make up the most significant part of the ash content. It should be noted that the terms ash and mineral matter are not synonymous. Ash, as stated previously, is the residue left after burning a quantity of coal in the presence of air. The amount

of mineral matter present in a coal can be determined by a point count performed on a specially prepared coal sample using a petrographic microscope. A simpler method for determining mineral matter if the ash and total sulfur values are known is by using the Parr formula as follows:

$$\% MM = 1.08A + 0.55S$$

where *MM* is mineral matter, *A* is percentage of ash in the sample, and *S* is the percentage of total sulfur in the sample. The Parr formula is probably the method most widely used in the United States for determining mineral matter content.

The amount of ash contained in a coal, as well as the ash's composition, affect the coal's performance and therefore its success in the marketplace. Even in very clean coals the ash content may be 2 to 3% and ash contents of 10% or more are not uncommon in many productive coal beds. Carbonaceous material in the coal bed that contains excessive ash is frequently termed bone, bone coal, carbonaceous shale, black shale, rash, or any of a number of other locally used terms. The greater the ash content of a coal bed the lower is the heating value per unit weight of the coal, so that, in higher ash coal, more coal is required to produce a given amount of heat and disposal of the ash residue also becomes a problem. The ash content of a coal usually can be lessened by "washing" the coal in coal preparation plants. This usually entails grinding the coal to a specified size, then suspending it in a liquid with a specific gravity intermediate between that of coal and the mineral matter so that the mineral matter tends to sink in the solution and the coal tends to float. By repeating this procedure several times, a significant part of the mineral matter content can be removed from the coal.

Ash varies greatly in composition. It may contain varying amounts of silica and alumina derived from detrital minerals; iron oxides from siderite, pyrite, and marcasite; calcium oxides and carbonates from siderite; iron sulfide from pyrite and marcasite; and magnesium, sodium, potassium, phosphorus, and a wide range of trace elements (Tiemann, 1973). Ash fusion temperatures, a measure of the temperatures at which coal ash begins to deform, softens, and becomes fluid, are important coal quality parameters that determine how the ash residue from a given coal will react when it is burned. Ash begins to deform at temperatures that range from 950° to 1700°C (1750° to 3100°F). Ash with fusion temperatures at the lower end of this spectrum is desirable in certain types of furnaces where ash is removed from the bottom in a liquid state but is undesirable in static fuel bed furnaces where removal of the residue is a difficult and costly process. Pyrite and marcasite (FeS₂), siderite (FeCO₃), calcite (CaCO₃), and other carbonate minerals are frequently responsible for low fusion temperatures in ash, whereas high silica or alumina contents are associated with higher fusion temperatures.

Calorific Value: In the ASTM system, calorific value is one of the primary rank-defining parameters for bituminous, subbituminous, and lignitic coals. Calorific value is usually reported in British thermal units per pound, or calories per gram, and can be easily converted from one system to the other.

Coal used for steam electric generation is sometimes sold at a fixed rate per million British thermal units with penalties for excess ash or sulfur (Wier, 1976). Because many contracts specify calorific value on an "as-received" basis and most analytical results are reported on a "dry" basis, dry values must be converted to "as-received" values by means of the following formula:

$$\text{Btu (as received)} = \text{Btu (dry)} \frac{100 - \text{moisture } \%}{100} \quad (\text{Tiemann, 1973})$$

The conversion formula contains percent moisture as a term, so the importance of accurate moisture values cannot be overstated.

Sulfur: Sulfur presents numerous problems in coal utilization. In combustion applications it can cause corrosion in the boiler or the buildup of heavy fouling in the boiler tubes. Large amounts of SO₂ are also generated upon combustion and may contribute to atmospheric pollution unless removed by limestone-based stack scrubbers. The same potential corrosion and pollution problems also apply to the liquefaction, gasification, and coking processes with the additional concern that unacceptably high levels of sulfur might be passed along through the coke to the iron and steel resulting in an inferior product (Ward, 1984).

Three commonly recognized forms of sulfur in coal are sulfate sulfur, pyritic sulfur, and organic sulfur. Of these, sulfate is the least important. In fact, sulfate sulfur contents are frequently on the order of 0.1%. Large sulfate values are sometimes indicative of a weathered sample. Relative amounts of pyritic and organic sulfur vary widely; in some coals total sulfur content is almost all organic whereas in other coals it is virtually all pyritic. It is important to analytically distinguish between organic and pyritic sulfur in coal because at least some of the pyritic sulfur can be removed by specific gravity separation methods. Pyritic sulfur occurs in the minerals pyrite and marcasite and, depending on the particle size of these minerals and the size to which the coal is crushed, half or more of this sulfur can be eliminated. That portion of the pyritic sulfur that occurs in finely disseminated form throughout the coal cannot be removed by specific gravity separation methods. The organic sulfur constituent is part of the hydrocarbon structure of the coal and cannot be removed by conventional coal cleaning technology. Although promising laboratory techniques designed to remove organic sulfur are under investigation, no commercially feasible process currently is available. Until washability tests are performed which can provide specific data, Wier (1976) advocates taking the sum of the organic sulfur content and one-half the pyritic sulfur content as a preliminary indicator of the final total sulfur content of the cleaned coal. Generally, only coals with low sulfur contents are used for steam electric generation. Average sulfur contents of coals received at US powerplants of 50 MW or greater generating capacity for the months October through December 1986 ranged from 0.16 to 5.6%. The overall average sulfur content of coal received at these same plants during the same period was 1.36% (US Dept. of Energy, 1987). Variations in maximum allowable sulfur contents in different areas are due primarily to differences in local regulations and to the presence of stack scrubbers at some facilities. The practice of blending different coals to achieve required specifications allows the use of some higher sulfur coals that would not otherwise be suitable for steam-electric generation.

Likewise, in coke production, the use of a high sulfur coal results in a decrease in the amount of coke that can be produced from a given amount of coal. Coal that cannot be cleaned to a sulfur content of less than 1.5% is not likely to be used, even as a blend, for coke production.

Free Swelling Index: Another commonly performed analytical procedure for coal is the determination of the free swelling index (FSI). The FSI is considered useful, although not definitive, in evaluating the coking properties of a coal.

It is a measure of the volume increase of a coal when it is heated under specific conditions and is reported in numbers from 0 to 9, with the higher values considered superior from a coking standpoint. FSI values generally increase with rank up to the anthracite rank but values within a given rank may vary widely. Generally speaking, coals with FSI values of 2 or less probably are not suitable for coke production and various users may require higher minimum FSI values for their specific equipment than others. Other tests that are used to predict the coking potential of a given coal include the Audibert-Arnu dilatometer, Gieseler plastometer, and Gray-King coke type, but the FSI is still the most commonly reported procedure of its type.

Ultimate Analysis: Ultimate analysis determines the percentages of the major constituent elements of coal. Determinations of hydrogen, carbon, nitrogen, oxygen, and total sulfur are reported. Typically, ultimate analyses are not performed on all coal samples but only on a representative number of samples. Data from ultimate analyses are used principally for research purposes and in certain classification systems, although there are commercial and industrial applications of the data. Specifically, ratios of carbon, hydrogen, and oxygen values are used to determine coal rank and as an aid in determining a coal's suitability for coke manufac-

ture, gasification, or liquefaction. Data on oxygen content also are used in calculating boiler efficiencies.

Nitrogen present in the coal may react to form ammonium compounds when coal is carbonized in the coking process. These compounds can be extracted and marketed as fertilizer or for use in the manufacture of nitric acid. Ammonium compounds are also formed in the gasification and liquefaction processes. Their formation, however, utilizes some of the available hydrogen that would otherwise be used in the formation of the more valuable hydrocarbon end products. Also, during coal combustion, nitrogen forms oxides which become atmospheric pollutants when released. For these reasons, low nitrogen contents are usually preferred in coal (Ward, 1984).

Other elements for which analyses are commonly sought include chlorine and phosphorus. Chlorine contributes to corrosion and fouling problems and possibly to atmospheric pollution. A knowledge of the chlorine content is also essential in determining other parameters, including total sulfur. Phosphorus, which is concentrated primarily in the mineral matter, is undesirable in coking coals because, like sulfur, it can contaminate the steel end product.

Trace Elements: Most coals contain a wide range of trace elements, some of which tend to concentrate in the organic

faction of the coal, while others have an inorganic affinity and are concentrated in the mineral matter. In some cases, trace element suites are distinctive enough to serve as aids in seam correlation or as indicators of the depositional environment. Boron, in particular, is more strongly associated with coals formed under marine influences. Some trace elements may act as catalysts or inhibitors during the complex reactions involved in coal conversion and may be transferred to the end products of those processes. Trace elements may also be released to the environment through combustion or through the weathering of the coal ash. Not all of the elements released into the environment are harmful but concentrations of toxic elements such as lead, arsenic, cadmium, or mercury might preclude the use of certain coals rich in those elements. Alternatively, other trace elements may be considered as potentially marketable byproducts of coal utilization. A list of trace elements and their concentrations in coals from different coal regions in the United States and Australia is given in Table 3.

Application of Coal Petrology: Coal petrology is the study by direct examination, usually microscopically, of the organic and inorganic components of coal. Petrologic studies form the basis for a broad range of relatively new techniques which have technologic applications of importance to those involved in coal exploration. For a thorough treatment of the subject, see Bustin, et al. (1985) from which the following comments are condensed.

Coal is a heterogeneous substance that is composed of components analogous to the minerals that are the constituents of inorganically derived rocks. These components are termed macerals and differ widely in physical and chemical properties and in their response to different technological processes. A knowledge of the petrographic composition of a given coal bed will allow the explorationist to predict its behavior in certain applications.

One area of technological application of coal petrology is in the area of coal cleaning by float-sink separation. Microscopic observations of the degree of intergrowth of the organic and inorganic constituents in both the float and sink fractions will indicate whether crushing to a finer size will increase the clean coal yield. Also, observing the type, distribution, and degree of intergrowth of the sulfur will give a preliminary indication of the probable methods of cleaning.

Another area where petrographic techniques have come to play a key role is in the production of coke. Through the employment of these techniques, predictions can be made concerning a coal's fluidity, FSI, and volatile matter content. Also, extensive research efforts through the years have shown that coal bed constituents can be classified as reactive or inert for given processes and that the information could be quantified to the point that the coal's behavior can be predicted with some accuracy. Two salient concepts resulting from these research efforts concerning coke quality prediction are: (1) an optimum mix of reactive to inert components of a given rank of coal will produce the best coke and (2) the percentages of this optimum mix will vary with rank. The importance of petrographic analysis to the steel industry is best illustrated by the fact that most steel producers now routinely conduct petrographic analyses to monitor blend quality and to evaluate new coals.

Although nearly 90% of the coal consumed in North America is used for combustion with most of that amount used for the generation of electricity, petrology has not played a significant role in the identification of desirable combustion characteristics. The primary reason for this is that factors most significant in defining the suitability of a coal for com-

bustion are either not directly measurable by petrographic techniques or they are more easily determined by other methods. Even so, some useful relationships have been identified through petrologic studies and it is an area of continuing research.

Finally, coal conversion technologies (primarily liquefaction) utilize petrographic data in identifying optimal coals for conversion. Rank and ratio of reactive to inert constituents are primary factors in determining a coal's suitability for conversion.

2.7 Placer

WILLIAM H. BREEDING

OCCURRENCE OF PLACERS

Placers are deposited by the action of water or wind. Aeolian or wind-deposited placers are generally not of commercial tenor, at least on any large scale, and will not receive further attention in this section.

Water-deposited placers include most placers mined commercially in the world today. Engineering data relates that the carrying power of water varies as the sixth power of its velocity. Whether carrying capacity varies as the fifth or sixth power, it will be appreciated that minor changes in velocity change the carrying capacity of a stream dramatically.

In planning land developments today, consideration is given to the effects of 25-year storms and 100-year storms, i.e., the severest storm to occur in those periods. When one thinks in terms of geological time, there are also 1,000-year storms and 10,000-year storms. Some of us have been privileged to see the results of very severe storms in our lifetimes, when brooks that one stepped over one day became raging torrents transporting 27-t (30-st) boulders the next. Severe storms result in major earth movements. Subsequent stream flows cause reconcentration of storm-deposited materials.

It is assumed that readers are familiar with the criteria that streams above a certain velocity will erode stream banks and bottoms, that streams at a certain velocity will transport suspended material, and that streams below a certain velocity will deposit transported material. Fine materials are, of course, deposited at lower velocities than coarse materials.

In accordance with the laws of hindered settling, coarse particles (gravel and coarse sand) will settle in general relationship to their specific gravities. Particle size and shape have effects but are subordinate to specific gravity. Moderately sized particles (sand) will settle similarly. Fine particles (slimes) have greater surface area per unit of mass than coarse particles, and the gravity component is limited by surface effects.

Heavy mineral concentrations may be expected to occur where streams lose velocity. Streams lose velocity when their gradients become flatter, where they change course, or deepen. More specifically, where a stream emerges from a canyon, on the inside of bends in a watercourse, or in deeper pools or "pot holes." These are the traditional places that placer miners look for concentrations.

Over the tens or hundreds of thousands or more years during which a placer is in formation, stream courses change and sites of heavy mineral deposition change. Glass models of placer deposits, based on extensive drilling results, have shown concentrations in similar patterns but at different sites. Certain levels of deposition are richer than others, and reflect the higher heavy mineral content transported during those periods of deposition.

In shallower placers the highest concentrations of heavy minerals are often on bedrock, which may be defined as the firm base on which alluvial material is deposited.

Ancient and Recent Placers

The division between ancient and less ancient and recent placers has never been established precisely to the author's knowledge. In some parts of the world ancient placers are

called paleo-channels (Brazil); in others they may be called tertiary channels (California) reflecting the period of depositions. Many placers fall in the time frame between carbon-14 dating and potassium-argon dating.

It is believed that the tertiary placers of California were deposited 8 to 65 million years ago (Lindgren, *The Tertiary Gravels of the Sierra Nevada of California*, USGS Professionals Paper 73-1911) before and during the uplift of the current Sierra Nevada range. During this period, stream systems eroded auriferous sections of the western slope. The tertiary rivers were subsequently covered with volcanic ash, volcanic flows and later, alluvials. Today, the tertiary channels may be covered with a hundred to many hundreds of feet of later material. In general, channels in the headwater areas are higher in heavier mineral content. Channels are often narrower in headwater areas and coarse gravel and boulders prevail. Subsequent faulting and displacement may change original gradients, and add to the miner's and explorationist's problems.

Sites where recent drainage cut tertiary channels in California were first located and mined during the 1850–1884 period. The scale of the workings of that period is little appreciated today. Over 8046 km (5000 miles) of ditches carried water to hydraulic monitors that excavated 0.038 km³ (50 million cu yd) of material annually, and discharged tailings into the river systems. A court order suspended this practice in 1884.

The Ballarat/Bendigo area in Victoria, Australia, is another site of ancient placers which is well described in literature.

When areas of the world are first explored and developed by ambitious men, placer deposits, especially gold placer deposits, are among the first to receive attention. The gold fields of California in 1849, the Klondike of the Yukon in 1898, Nome, Alaska beaches in the early 1900s, the South Island of New Zealand in the later 1800s, and New South Wales in the late 1800s are a few examples. The placer tin fields of Southeast Asia followed in the 1900s. Lucrative gold fields in Colombia, South America were developed in the 1908–1920 period, expanded in the 1930s and late 1940s, and continue to produce today. The placer tin fields of the Brazilian Amazon were first recognized in the 1960s and production continues to expand annually.

What are known as heavy mineral placers, generally beach sand minerals not of the precious metals (Au, Pt) or high value specific gravities (SnO₂) types, have been developed in this century. They include rutile, ilmenite, and related minerals, zircon and monazite.

Large and rich placers may occur in areas where lode gold mines are few or nonexistent. Placer areas west of the Sierra Nevada range of California lie below serpentine belts where lode mines have been of the small vein type with rich localized ore shoots, often called *pocket mines*. In placer areas of Alaska, there have been few lode mines. In British Columbia, gold mines of size have been infrequent. In Colombia, substantial lode gold mines have been very few. In New Zealand, the best placer areas of the South Island have supported few lode mines. In Bolivia, the richest gold placers have been found in ancient conglomerates, or in more recent

placers resulting from their erosion and redeposition. Some placers have resulted from the erosion and direct deposition of vein materials, but they have been small. Most of the great placer gold fields of the world are second or third generation placers, i.e., the auriferous material has been eroded and redeposited two or three times.

Ancient placers may lie on varying grades due to subsequent tectonic movements. More recent placers may lie on grades of 0.5 to 3% or more. Smaller deposits with coarse gravel may be expected at the steeper gradients, and deposits with more sand and silt at the flatter gradients.

In areas of moderate to heavy rainfall, 76 to 760 cm (30 to 300 in.) per year, placers may be expected to contain rounded well-washed gravels and sands. Gravel with a shingled appearance on river bars provides an excellent environment for the collection of placer gold. In areas of lower rainfall, material may be subangular and contain more clay resulting from major movements during infrequent floods. In semiarid areas, alluvial fans, formed where intermittent streams emerge from hills and discharge onto flood plains, may contain heavy minerals. Fan deposits are found in Nevada, Arizona, and around lake basins in other states of the western United States. The monazite/zircon/ilmenite deposits of the Cascade basin of Idaho, which were mined with AEC/GSA support in the 1950s, were of this type.

In addition to placers deposited by the action of water, there are in-situ deposits which have been enriched by the erosion of lighter material accompanying the heavy minerals. When tin-bearing granites decompose and are subjected to erosion, the feldspars become clays and are washed away by rains and stream action. Quartz fragments remain behind along with heavier cassiterite. Unless quartz fragments are considerably coarser than the cassiterite, they too will be washed away, leaving rich concentrations of cassiterite behind.

Outcroppings of gold-bearing gossans subjected to weathering are other examples of in-situ enrichment. The enriched upper sectors are often mined profitably, but profitability generally declines rapidly as material becomes harder, and in-situ enrichment decreases. These surface enrichments have been called saprolitic in areas of the southeastern US.

Enrichments may also occur on the slopes between in-situ or *eluvial* deposits and stream bed *alluvial* deposits. These slope deposits are referred to as *colluvial* deposits.

Minerals found in placers in economic concentrations include gold, platinum, cassiterite, rutile, ilmenite, zircon, monazite, tantalite, columbite, diamonds (gem and industrial), gemstones (other than diamonds), abrasives (garnet and carborundum), chromite, and others in minor amounts. Silica and other light residuals may be salable.

POTENTIAL PLACERS

It is unlikely that high grade and significant placers of traditional minerals will be found at shallow depths along recent river systems with the exceptions of unexplored areas or remote areas without infrastructure.

Potential placers are more likely to be encountered: (1) in ancient or paleo channels, (2) at depth or with other problems not economically solved by earlier operators or equipment, and (3) in areas inaccessible to earlier engineers, or without infrastructure to support an economical operation. Minerals which previously had no commercial value add another factor.

To appraise the potential of a placer without expending major sums for equipment requires experienced judgment supported by convincing evidence of potential (usually samples). Deposits *above the water table* can be initially sampled for acceptable cost by methods described in Chapter 3 of this volume. For deposits *below the water table*, churn drilling is reliable, but time consuming, and adequate personnel and equipment may not be available for an initial appraisal. Caisson shafting is slow and generally confined to the gathering of confirmatory and supplementary data. Information is needed on the extent, depth, and nature of the placer material.

Seismic surveying is the most effective of the geophysical techniques for placer work; however, to be reliable, it should be referenced to certain known depths (from drilling, shafting, or tunneling). Properly undertaken and supervised, it will provide information on the depth and character of placer material. Seismic velocity is generally an adequate measure of material density, difficulty of excavation, and angle of repose; however, experience has shown that without adequate referencing and supervision, results can be misleading.

Double casing drills of both the direct and reverse circulation types, using water or air for recovery media, are much faster than churn drills. In sandy deposits, they have proven satisfactory for both qualitative and quantitative evaluations. In coarse placer gravel, most experienced placer engineers do not consider them satisfactory for quantitative evaluation; for qualitative results, they can be useful.

Rotary drills will provide information on the depths of placer materials, and will penetrate hard capping (such as lava flows) materials rapidly. Information on heavy mineral content is at best qualitative, i.e., it will show the existence of heavy minerals and if there is much or little, but not the precise quantities.

Vibrating drills are limited to the depths required to pack the core barrel. If a hole will stand open without caving, the coring drill may be reinserted. If the hole will not stand, the problems of casing the holes must be solved. These drills have been used to sample the first sections below the ocean floor.

Auger or post-hole type drills with highly portable, geared gasoline engine drives are effective above the water table, where holes will remain open. In tin-bearing sandy clays, they have been used to depths of 6 to 9 m (20 to 30 ft) effectively. Information on the depth and nature of material is obtained, and unless holes cave (when passing sand lenses, etc.), results are definitely qualitative and semi-quantitative.

It is not the purpose of this section to deal with operating costs, but in establishing what is a potential placer, attention must be given to size and the economics of scale. If all supervisory and supporting costs must be charged to one small producing unit, costs will be high. If there are several operating units, supervisory and supporting costs may be distributed. Experience has shown that adding a second (similar) operating unit will reduce costs of the second unit by about one-third, or one-sixth for each of the two units.

Two items that will severely increase operating costs are boulders and clay. Buried logs, acid water, and flooding are other considerations, but they can usually be handled by proper designs. In evaluating any placer, careful attention must be given to the quantity and size of boulders, and quantity and nature of clays (will they disintegrate under high pressure water jets; will they settle in decantation basins, etc.).

In assessing the potential of a placer, the evaluator is seeking to justify the cost of the next page of evaluation.

ECONOMIC PLACERS

When a potential placer is of great richness, considerable tolerance can be allowed in evaluating valuable mineral content. When a placer is very poor in valuable mineral content, it may be rejected without further work. Unfortunately, many potential placers are in the intermediate range of just good enough or almost good enough, and require very careful evaluation.

In placer evaluation, the evaluator should relate mineral content to volume. What is needed is mineral content per cubic yard or meter. Weighing bulk placer material is unrewarding and can be misleading. Weights of placer material will vary greatly with moisture content and with the nature of the material. Placer material normally weighs from 2500 lb to 3700 lb per cubic yard. For rough conversions, one cubic yard may be considered to weigh 1.5 short tons, and one cubic meter may be considered to weigh 2.0 short tons.

In evaluating placer material *above the water table* firm enough to stand unsupported, channel sampling is effective, requiring little equipment and more care than great expertise. As placers are deposited at low gradients, channels should be cut vertically. To limit the excavation of exposed banks, vertical cuts may be stepped, i.e., offset between elevations.

For evaluations made in traditional US or English units (milligrams of gold or pounds of tin per cubic yard), channels 6 in. x 12 in. have proven effective. If material is fine (limited coarse gravel), smaller channels may be used. If material is coarser, smaller channels are unadvisable and larger channels are worth considering. Sampled material is generally collected every 1.2 m (4 ft), or by strata, and concentrated by rocker and/or panning. Tailings from an entire channel should be collected and checked for values by repanning or tabling (if such equipment is available). Checking fine tailings is especially advisable when very fine heavy minerals (gold, cassiterite, rutile, etc.) are known to be present.

Where exposed banks are not available, but placer material is above the water table, shafts or trenches may be excavated. In shallower deposits [to about 6 m (20 ft)], trenches may be dug with a backhoe, or shafts may be excavated to that depth or deeper (with a larger hoe or by benching down). Bulldozer trenches are used but are generally more expensive and less acceptable environmentally.

Channel sampling of shafts or trenches is rapid, and provides information on the stratification of mineral values. If the responsibility of the samplers is not well established, different samplers may be used on opposite sides of a shaft or trench. Subsequent treatment of the entire volume excavated from a trench or shafts may be passed through sizing tests and a pilot plant (with a circuit similar to a commercial recovery circuit). The information obtained from bulk sample treatment will be helpful in designing a commercial plant. If material does not disintegrate readily in a small (pilot-plant-size) trommel, it may do so in a large one.

When sampling old hydraulic pits or other exposed banks, it is important to cut the banks to fresh surfaces. Heavier gold or cassiterite may fall from long-exposed surfaces, resulting in under-evaluations. Further, in old hydraulic pits, the former operators probably mined the best exposed material, and exposed faces may under-represent the remaining deposit. A few shafts excavated back from the face should provide useful supplementary data.

Sampling more than a few feet below the water table requires casing the hole or pit. Proven methods include Banka or Empire drilling, hand and mechanized churn drilling, and caisson shafting or drilling.

Banka drilling is an effective method in shallow alluvials, and where coarse and tight gravels are not prevalent. Casing is flush-threaded, and the drilling shoe at the lower end of the casing is sometimes serrated. Pressure is applied at the top of casing by men standing on a platform and by men dropping a weight on the casing head. The casing is rotated while pressure is applied. After a suitable casing advance, which is generally limited to 1 ft, or 0.25 or 0.50 m (depending upon the terrain and mineral sought) in economic ground, core removal is undertaken. In overburden or low-grade strata, longer drives may be used to increase drilling speed, but long drives generally result in poor core recovery and affect the accuracy of sampling. It is important to remember that the purpose of most placer drilling is to obtain an accurate sample, not to drill rapidly.

Core removal in gravel is generally by bailer, which is a piece of pipe with a flap or ball valve at the lower end and a plunger which pulls material into the barrel. In clayey ground, clay pumps, which are often pieces of pipe, open at the bottom, with side slots for core removal, may be used. Augers have been used at shallower depths, but are generally not the favored tool of experienced churn drillers.

Core removal or pumping usually proceeds until the casing has been cleared to the level of the drive shoe. Exceptions are: (1) when drilling in loose sand (often called rising ground) and a plug is left in the casing to reduce the inflow of alluvium, and (2) when drilling in very hard ground where it is impossible to drive the casing deeper within acceptable time. It is poor practice to pump or drill below the drive shoe; however, there are times when there is no other solution. When drilling below the drive shoe, appropriate notation must be made on the drill log, and positive corrections are not advisable.

In tight placer ground, there is an intermediate step between driving casing and pumping which consists of loosening material in the casing by dropping a chisel, star, or other shaped bit upon it. The bit breaks up placer material, including rocks, and also causes slimes by disintegrating clays. Because of the sliming effect and the possibility that stones may be driven downward, it is important to measure the height of material in the casing before and after pumping. Two or more measurements may be made to ascertain that pumping has reached the proper level before it is suspended.

The sequences in Banka or churn drilling are: (1) advance casing, (2) measure core rise in the casing, (3) loosen the core if necessary, (4) remove the core, (5) measure to ascertain that enough core has been removed, and (6) measure the core removed (volumetrically). Core removed from the casing is dumped into a trough and washed to a measuring box or pipe. For simplicity, some engineers use a pipe of drill casing for a measuring box. Overflow from the measuring box should be decanted into tubs and the slimes checked for mineral content. Slime volume may be added to the box or pipe measurement. Except in rising ground, core rise (the difference between before pumping and after pumping measurements) is generally greater than box or pipe measurement.

Hand and powered churn drills use the same basic procedures as the Banka drills, but casing is larger, especially for the powered drills, drilling shoes are not serrated, casing is rotated infrequently, casing couplings are used, and tools are lowered and removed by winch. Driving the casing is accomplished by dropping a heavy hammer on the drill (driving) head at the top of the casing. The heavy hammer is a pair of blocks bolted to the drill stem.

The standard placer exploration tool for over 50 years

has been the churn drill (Keystone, Bucyrus, Speed-Star, Cyclone, etc.) with 152 mm (6 in.) casing and a 191 mm (7.5 in.) drive shoe (see Fig. 1). Thirty years ago, it was common practice to use manila rope with drill tools, but recent practice uses left lay wire rope (to keep the tool joints tight). An experienced driller will bounce the drill bit on material in the casing, using the spring in the rope to keep from driving material downward.

On drills using 152 mm (6 in.) casing, cable is generally 19 mm ($\frac{3}{4}$ in.) [though some use 16 mm ($\frac{5}{8}$ in.)] and cable on the bailers is 9.5 mm ($\frac{3}{8}$ in.). Crayon marks on the wire ropes indicate the distance to the end of the drill bit or bailer, and are used to measure core levels in the casing. Casing is marked at 1-ft (or appropriate meter*) intervals from the drill shoe before use.

Casing sizes vary slightly, but assuming a 6 in. interior diameter and a 7.5 in. drill shoe,

$$\left(\frac{7.5 \text{ in.}}{2}\right)^2 = 44.18 \text{ sq in. of drill shoe interior}$$

$$\left(\frac{6.0 \text{ in.}}{2}\right)^2 = 28.27 \text{ sq in. of drill pipe interior}$$

$$\frac{44.18 \text{ sq in.}}{144 \text{ sq in./sq ft}} = 0.3068 \text{ sq ft}$$

$$\frac{27 \text{ cu ft/cu yd}}{0.3068} = 88 \text{ ft of drive/cu yd}$$

Eighty-eight feet per cubic yard is considered the theoretical drive required to provide one cubic yard of core; however, drill shoes wear and experience has shown that the theoretical evaluation may be adjusted to provide greater accuracy. In the last century, an engineer named Radford began using *100 feet of drive to equal one cubic yard of material*, and it has been accepted by many in the industry.

Dividing drive shoe area by drill pipe area:

$$\frac{44.18 \text{ sq in.}}{28.27 \text{ sq in.}} = 1.56 \text{ theoretical core rise in the drill pipe per unit of advance}$$

Correcting this factor for shoe wear:

$$1.56 \times 0.88 = 1.37 \text{ adjusted core rise}$$

After studying production and drilling results of several companies for several years, the author proposed that 1.4 ft of core rise for 1 ft of drive be accepted in place of the several variations in use, and this practice was adopted and has been in use by several companies for 25 years. Different factors are obviously in use for casing of substantially different sizes, but the principle is valid.

An area where engineers and companies have differed is in the correction of drilling results. One major company did not use positive correction of drilling results for deficient cores and production results averaged 10 to 15% above drilling estimates. Another group of companies used positive corrections and obtained results (for five to seven dredges) of very close to 100% of drilling estimates. Monthly recovery/prospecting factors would vary, but annual and longer term factors were extremely close to 100%. The method of

treating exceptionally high holes (correcting for the nugget effect) also affects recovery factors.

Log Correction Techniques

Four methods used by drilling organizations are:

1. No corrections: seldom used at present.
2. Corrections for rises or volume in entire hole.
3. Corrections for rises or volume in pay streaks.
4. Corrections for rises or volume in individual drives.

Generally, the most conservative correction, whether it be from box measurement or from core rise measurement, is used, i.e., the correction giving the greatest negative correction is used.

Under certain conditions, methods 2 and 3 may be adequate, or nearly adequate, but method 4 is the only one believed applicable in all circumstances.

When evaluating a *gold property* in a district where recent mining or professional prospecting information is not available, representative gold samples must be sized and weighed; average weights are then assigned to No. 1, 2, 3, and 4 colors. These estimated weights are used for corrections to individual drives, and the algebraic total of the corrections adjusted as follows:

$$\begin{aligned} \text{mgs/cu yd} &= \text{act. wt gold} + \text{corrections} \times \text{act wt} \div \\ &\quad \text{est. wt} \\ &\times \frac{\text{drive shoe factor}}{\text{dredging depth}} \end{aligned}$$

Permissible Corrections

Maximum Positive Corrections in general use are given as follows:

Co. A	= 42%
Co. B (recent)	= 50%
Co. C (old)	= to about 200%
Co. C	= later 0%
Co. D	= 240% (lower river areas)
	100% (upper river areas)
Co. E	= 0%

If no boulders are present, the use of positive corrections to 100% may be acceptable. If boulders are present, the use of positive corrections must be reduced or eliminated. Experienced engineers regard excessive positive corrections with caution.

Where hard, irregular bedrock is present, it is generally advisable to delete gold or tin recovered from the last foot or two of hole.

Similar corrections may be applied for *cassiterite (tin) evaluations*, but additional attention must be given to: (1) checking panners' tailings for fine tin, (2) checking coarse material for locked tin [passing + 9.5 mm ($\frac{3}{8}$ in.) material over heavy liquids is useful], and assaying samples. To avoid an excessive number of assays, material from various drives may be combined. If formations are relatively constant, errors should be minimal. If core recoveries and mineral content vary substantially, more assays are advisable.

If a 1-ft drive yields a core rise of 1.4 ft, there is no core correction. If a 1-ft drive yields a core rise of 1.7 ft, excess core has been recovered and a negative correction is applied of $1.4 \div 1.7$ or 0.82 to the values recovered. If a 1-ft drive yields a core rise of 1.1 ft, deficient core has been recovered and a positive correction is applied of $1.4 \div 1.1$ or 1.27 to the values recovered for that drive.

In gold prospecting, it is customary for the driller to estimate the quantity of gold recovered for each drive, and individual drives are corrected on that basis. Upon comple-

* Metric equivalents: in. $\times 25.4$ = mm; sq in. $\times 645.16$ = mm²; ft $\times 0.3048$ = m; sq ft $\times 0.09290304$ = m²; cu ft $\times 0.0283168$ = m³; cu yd $\times 0.7645549$ = m³.

Fig. 1. Placer churn drill

tion of the hole and log, all gold recovered from the hole is weighed and checked against the panner's estimate. A single correction of actual weight of gold-estimated weight of gold is then applied to cumulative corrections. If the driller is consistent in his estimating (high or low), there will be no error. To assist the panner in his estimating, sample colors (size 1, 2, 3 and 4) are weighed and displayed on a small backboard. In a new gold field, drillers and panners may err in their first estimates, and extra care must be taken; however, if estimates are high or low, there will be no residual error if estimating is on a consistent basis.

In estimating tin values, and especially where other heavy minerals of similar appearance are present, it is difficult to eyeball estimate tin content for individual drives. In this case various drives may be combined and the concentrate assayed. Some prospectors use the zinc block test to estimate tin content, but the author has found this practice inaccurate. If cores are consistent, several drives may be combined for corrections. If they are inconsistent, caution and probably more assays are required.

Most placer engineers amalgamate gold samples. Common practice is to put the sample of gold and black sand into a porcelain or agate mortar with chemically pure (C.P.) mercury, and to grind with a porcelain or agate pestal until all visible and, hopefully, all commercially recoverable gold has been amalgamated. Amalgam and residual mercury is then placed in a small crucible with nitric acid and heated on a hot plate. This operation should be conducted under a hood with exhaust fan. The remaining gold is annealed (by additional heating on a burner), cooled, washed, and weighed. Samples may be collected from a group of holes and assayed to determine gold fineness. Most placer gold (bullion) will average from 850 (85%) to 950 (95%) fine gold. Alloying metals are generally silver and copper.

Churn drilling by experienced drillers has yielded satisfactory results for placer mining for many years, but drilling expertise is needed, and is often in short supply. In new fields there is a need for additional supporting information on the nature of the mineral and material to be mined. Also, despite the use of heavier drills, hydraulic assists, welded casing, and other modest improvements, churn drilling remains a slow process.

To check and supply supporting information to churn drilling, caisson shafts have been used, and they are effective to depths of 12 or 15 m (40 or 50 ft), especially if labor costs are reasonable. One practice has been to cut a 0.3-m (1 ft)

cube of material every 0.3-m (ft) of advance (using a knife-edged box), and later to screen and process all material from the shaft. Air pumps in the shaft will dewater and provide needed ventilation. Marsh gases can accumulate in placer shafts. If telescoping casing is used, a 51 mm (2 in.) reduction in diameter for each 1.2 m (4 ft) section has been effective. A 102 cm (40 in.) diameter is about the smallest in which a man can work effectively.

During the past decade, caisson drills have been available and they provide very reassuring data on both mineral content and the nature of material to be mined. The data obtained can help avoid expensive mistakes and will permit the development of an efficient mining plan and the use of efficient equipment. The only problem with caisson drilling is the high cost of the equipment and the relatively high cost of its operation, at least until depreciated.

Caisson drills come in various sizes from 0.500 m (19.7 in.) to 2.0 m (78.7 in.) or even larger, and are currently made in Europe and used there and elsewhere for pier, bridge, and building foundations. Properly sized, they have reached depths of 183 m (600 ft). They have been found acceptable in diamond prospecting, where large samples are required, and for gold prospecting. They have encountered and passed cemented gravels several feet thick.

One effective machine (BADE, made in Germany) uses oscillating hydraulic jacks of 136 t (150 st) to turn 900 mm (2953 ft) casing 22.5° (see Fig. 2). Raising and lowering jacks are 90-t (100-st). To date, drilling to 114 m (375 ft) has been successfully undertaken, and depths of 137 m (450 ft) are anticipated. In very deep ground, larger casing diameters may be used in the upper sections of a hole, followed by reduced diameter for the entire greater depth.

Cores are normally extracted with hammer grabs of both clam shell (two-blade) and orange peel (three-blade) design. Bailers are available, but used infrequently. Heavy star bits and other drop breakers are necessary when cemented layers are encountered. It is practical to pass all cores through a pilot plant approximating a commercial recovery circuit, but cores should be measured upon extraction from the caisson. (Duplicate measuring pipes that discharge into the pilot plant are effective, and avoid drilling delays.) Caisson joints are flush and of patented design. Details are best obtained from suppliers. Progress is equal to, or better than, churn drill progress for known equipment.

Fig. 3 is a sample of a form used to record the calculation of drilling results.

2.8 Tar Sands Exploration and Geology

J. ALLEN HENNESSY

INTRODUCTION

Tar sand is a term applied to sand impregnated with oil, or more precisely, with a viscous hydrocarbon called bitumen. A more technically correct term than tar sand is oil sand or bituminous sand. However, the term tar sand has been widely used and has been given official status by the Alberta Oil and Gas Conservation Act, which defines tar sand as "a sand containing a highly viscous crude hydrocarbon material not recoverable in its natural state through a well or by ordinary oil production methods." In this section, these deposits will be referred to as oil sand, the term most frequently used for such deposits in scientific literature and within the industry.

These deposits of oil are very similar to conventional oil pools except in two significant ways: First, they are more viscous than conventional crude oils with an API (American Petroleum Institute) gravity of 5 to 15 degrees, compared to 25 to 40 degrees for conventional crude oil. The deposits in place have a viscosity such that the oil is immobile and will not move within the reservoir unless it is mobilized by heating or by a solvent. Secondly, the deposits of oil sand, especially in the case of those in the Athabasca region of Canada, are much larger than conventional oil pools. For example, the Athabasca deposit contains approximately 143 Gm³ (900 billion bbl) of bitumen in place, whereas the Prudhoe Bay oil field, which is one of the ten largest conventional oil pools in the world, contains only about 2.4 Gm³ (15 billion bbl) of oil. Because of their high viscosity, these oil sand deposits must be mined and the oil separated from the sand by a variety of techniques using either hot water or solvents. The grade and geometry of the known deposits are such that they lend themselves to exploitation by surface mining techniques. These deposits are also being studied for in situ recovery of oil but these efforts will not be discussed here since this volume is concerned with surface mining.

This section will discuss the exploration and evaluation of these minable oil deposits. The techniques for grass-roots exploration for these deposits are similar to those employed in the search for oil and other energy resources; that is, regional mapping, stratigraphic studies, geophysical surveys, and exploration drilling. Very large deposits of oil sand have already been located and the major task is the delineation and evaluation of these deposits. Consequently, the early or grass-roots exploration will not be discussed in detail here, however, the techniques of drilling and sampling the deposits to determine their grade and extent, and to develop a data base required for surface mining planning, will be examined.

LOCATION OF THE MAJOR RESOURCES

Deposits of oil sand are known throughout the world, with the largest and most thoroughly studied located in Canada, the United States, and Venezuela. The world's most significant deposits are located in the northeastern portion of the Province of Alberta, Canada (Fig. 1). These Cretaceous oil sand deposits of Alberta have an estimated 143 Gm³ (900 billion bbl) of in-place bitumen, which is almost twice the recoverable conventional oil reserves in the world. However, only 10% of these reserves in Alberta are close enough to the surface to be considered recoverable by surface mining

techniques. The Orinoco petroleum belt in Venezuela is probably the second largest oil sand resource in the world estimated to contain 111 Gm³ (700 billion bbl) of oil.

Oil sand occurrences are known to exist in 24 states within the United States; however, only in six of these states are there large enough deposits to conceivably support a commercial operation. These are located in Alabama, California, Kentucky, New Mexico, Texas, and Utah. Deposits in these six states are estimated to contain approximately 4.8 Gm³ (30 billion bbl) of oil with the deposit in Utah containing approximately 90% of these US reserves.

DEVELOPMENT OF OIL SAND DEPOSITS

The only commercial development of oil sand has taken place in the Province of Alberta, Canada. There are four major oil sand deposits in Alberta: the Athabasca, Cold Lake, Wabasca, and Peace River deposits. The Athabasca deposit is by far the largest and contains the only reserves shallow enough for surface mining. These deposits were initially discovered from outcrops of the oil sand along drainages, in which the bitumen would ooze from the surface when exposed to the sun.

There are two commercial operations using surface mining techniques to extract oil sand from the Athabasca deposit north of Fort McMurray, Alberta, Canada. These are the Great Canadian Oil Sands (GCOS) operation which is located along the Athabasca River, 40 km (25 miles) north of Fort McMurray and the Syncrude mining operation, located immediately adjacent to the GCOS lease. The GCOS lease has 100 Mm³ (630 million bbl) of recoverable oil and is being exploited at the rate of approximately 7 900 m³ (50,000 bbl) of synthetic crude oil per day. The overburden on the GCOS property averages about 15 m (49 ft) in thickness and is removed with a large bucket wheel excavator in conjunction with 136-t (150-st) trucks. The oil sand which averages about 50 m (164 ft) in thickness, is removed by large bucket wheel excavators and carried to the process plant by conveyors. The oil is removed from the sand using a hot water process. The GCOS plant went onstream in 1967 and achieved its design capacity of 7 200 m³ (45,000 bbl) of synthetic crude per day by 1970.

The Syncrude mine went into operation in the late 1970s with a design capacity of 19 800 m³ (125,000 bbl) of synthetic crude oil per day. The oil sand averages approximately 11 to 12% bitumen by weight. Approximately 1.8 t (2 st) of oil sand is needed to produce one barrel of synthetic crude. Adding the handling of overburden and tailings material, 4.5 t (5 st) of material need to be moved per barrel of crude. At a designed capacity of 19 900 m³ (125,000 bbl) per day, the Syncrude operation will handle more than 544 kt (600,000 st) of material per day.

Currently there are no commercial oil sand operations in the United States. However, studies and pilot plant testing are underway on deposits in Utah, California, and Kentucky.

GEOLOGY

Oil sand deposits consist of accumulations of heavy oil within the pore space of permeable reservoir rocks, such as sandstones or unconsolidated sands. They are essentially the

Fig. 1. Location of major oil sands deposits.

same geologically as conventional oil reservoirs, except that the hydrocarbon is much heavier and cannot be recovered with conventional oil wells. These deposits are subject to the same type of geological analysis as conventional oil reservoirs, such as studies of source rocks, reservoir rocks, oil migration history, trapping mechanisms, and oil maturation and differentiation. The percent of oil in an oil sand deposit is a direct function of the porosity and permeability of the host rock. The distribution of permeable zones is controlled by the distribution of porous sand bodies and interbedded shales or other impermeable strata. Most oil sand deposits are thought to be formed when oil migrates from a source rock into a permeable reservoir rock and is exposed to water washing and a lessening of pressure with the consequential loss of the light hydrocarbons, leaving a heavy residue—the bitumen in the oil sands deposit. However, there are two schools of thought regarding the origin of the oil in these deposits. One theory is that the parent petroleum was a thermally mature crude similar to conventional crude oil that has migrated from some geographically remote source rock into the sand deposits and been subjected to biodegradation and water washing to produce the oil sand deposit. The other theory postulates that the parent petroleum was an immature crude and has a source within the same formation or very close to the oil sand deposit. Whatever the source, it is clear that the oil was much less viscous at the time it entered the reservoir as it occupies all the porous and permeable zones within the reservoir.

One characteristic of oil sands that is important to the selection of processing techniques is whether the sand is water wet or oil wet. In the case of water wet oil sand, as in the Athabasca deposits, there is a thin film of water separating the bitumen from the sand grain (Fig. 2), which allows the bitumen to be removed by a hot extraction process. In the case of oil wet sands, the oil is in direct contact with the sand grains and is more difficult to remove, usually necessitating a solvent extraction process.

Most oil sand deposits are located in alluvial or deltaic sandstones near the edge of a large basin (Fig. 3).

These alluvial and deltaic environments usually contain a variety of sedimentary units with differing amounts of porosity and permeability. This variety results in a nonhomogeneous oil sand deposit. The oil content is directly proportional to the porosity of the host rock and its deposition was

controlled by the permeability. A study of the depositional environments can lead to an understanding of the variability in the deposit.

Any exploration or development effort should include a thorough study of the sedimentology and a reconstruction of the depositional history of the deposit area.

EXPLORATION TECHNIQUES

Oil sand deposits are essentially the same as conventional oil reserves except that they are more viscous because of the loss of light hydrocarbons. Exploration techniques used to locate these deposits are consequently the same as those used for conventional oil reservoirs. Regional or grass-root methods include identification of source-rocks, location of reservoir rocks with high porosity and permeability, and identification of traps in the reservoir rocks.

Fig. 2. Structure of typical oil sands particles (McConville, 1975).

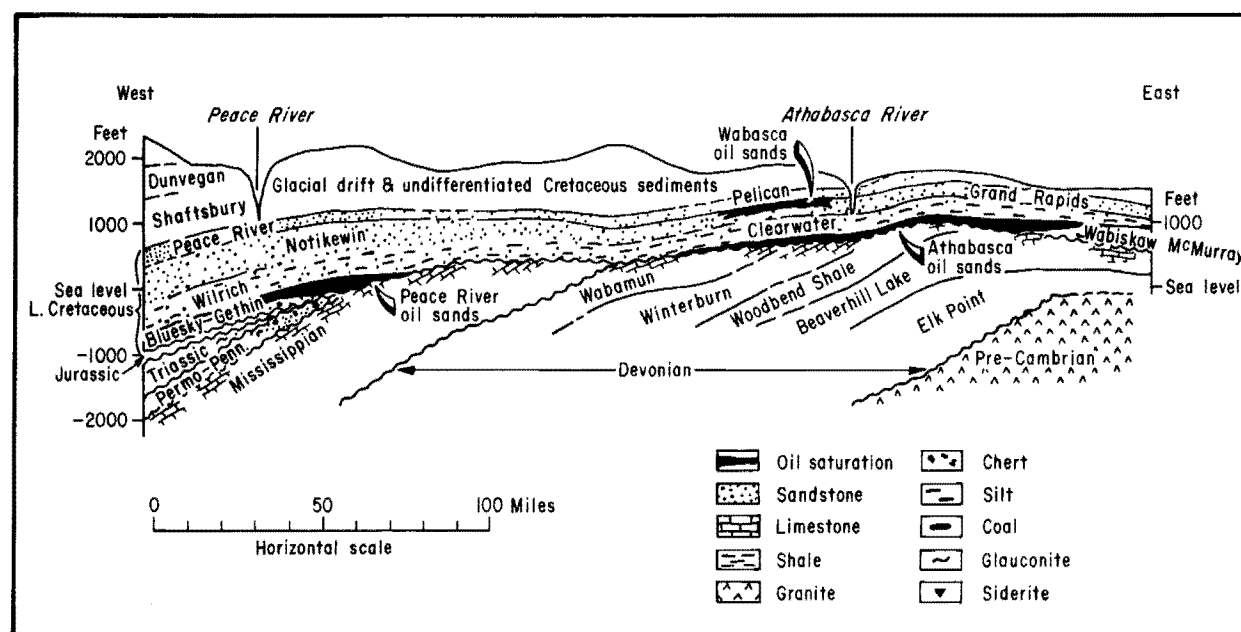

Fig. 3. Schematic geological east-west cross section of Northern Alberta oil sands (McConville, 1975).

DRILLING

Core drilling is the most widely accepted method for sampling oil sand deposits, although rotary drilling with electric logging and bulk sampling are also used.

The most common core size is 63.5 to 76.2 mm (2.5 to 3 in.) in diameter. The core should be described by a geologist and the intervals containing significant bitumen should be sampled by geologic unit or in 3 m (10 ft) intervals or less. Drill spacing varies from 1.6 km to 76 m (1 mile to 250 ft) depending on the deposit and the purpose of the drilling.

Reconnaissance drilling is often done on approximately 1.6 km (1 mile) centers with fill-in drilling at 0.8 km (0.5 mile) and 0.4 km (0.25 mile) centers as more detailed exploration proceeds. Final drilling for areas to be mined in the first five years is usually carried out on a spacing of 76 to 152 m (250 to 500 ft), depending on the variability of the deposit.

Rotary drilling with sampling of cuttings every 0.6 to 1.5 m (2 to 5 ft) followed by electric logging is also used extensively on some deposits with good results. Rotary drilling and logging must always be supplemented with core drilling and it is advisable to have some twinned core and rotary holes for comparison of results.

Whether rotary or core drilling is used, geophysical logging of the holes is usually performed.

The typical suite of logs run on an oil sand drill hole include caliper, natural gamma, gamma-gamma density, neutron, and resistivity. The interpretation of these logs with respect to bitumen content will vary from deposit to deposit and from place to place within a deposit depending on the characteristics of the host rock. In general, the natural gamma and the gamma-gamma density are most useful for determining lithology and the resistivity and neutron logs are useful in determining the amount of hydrocarbon in a unit. The resistivity of a unit is inversely proportional to the amount of water present. As the water decreases in an oil sand unit, the bitumen increases. Therefore the resistivity increases as the percent of bitumen increases. The neutron

log responds to the hydrogen and to a lesser extent to the amount of carbon in a formation. It can therefore be a useful direct measure of the bitumen (hydrocarbon) present. The neutron log is also useful in detecting zones of gas.

The natural gamma and density logs can also be correlated to the percent of bitumen in an oil sand unit. There is usually a decrease in bitumen content with increased natural gamma count. This is due to the fact that the natural gamma responds to radioactive elements such as potassium isotopes present in clays, and as the clay content increases, the porosity and permeability decrease, resulting in a lower bitumen content. The bitumen saturation tends to increase as the density of an oil sands unit decreases. The decrease in density is often due to an increase in porosity in the formation resulting in an increase in the amount of bitumen in the pore space.

These relationships are generalizations that will have exception in some deposits. The response of geophysical logs must be correlated with drill cores for each deposit and for various areas within a single deposit to insure reliable interpretation of the logs.

ASSAYING

One of the most important aspects of oil sands exploration is the determination of the amount of oil present in the rock.

There are three methods in common use for determining the amount of bitumen in an oil sand sample: the Dean-Stark method, the Soxhlet method, and the modified Fisher assay. In some cases, a modification of these standard procedures is used for a particular deposit but the vast majority of samples are assayed using one of these standard techniques.

The Dean-Stark method is the most widely used analytical technique for determining the weight percent of oil in an oil sand sample. The technique consists of weighing the sample, then removing the bitumen and water with a hot solvent, such as toluene. The water evaporates and is trapped and weighed. The bitumen is lost in the solvent. The re-

maining sample is weighed and the weight percent of bitumen is determined by difference.

The Soxlet technique is similar to the Dean-Stark method except that the water is lost and the bitumen is recovered and measured directly. More specifically, the sample is weighed and hot solvent is percolated through the sample to remove the hydrocarbon. The solvent is then boiled off leaving the oil or bitumen which is then weighed directly. The method allows the oil to be tested for viscosity and other properties. It is advisable to run both the Dean-Stark and Soxlet on splits of the same sample so that both the water content and the properties of the oil can be measured on at least a few samples.

A third and less costly method for determining the amount of oil in a sample is to heat it in a retort and measure the amount of oil that comes out. This method is the modified Fisher assay used for oil shale. With this method there may be some small losses of the hydrocarbons or some hydrocarbon may remain in the sample. Therefore, duplicate samples should be tested using the Dean-Stark or Soxlet methods. Results from retorting have been quite successful on some deposits resulting in considerable savings in analytical costs.

Another indirect method of determining the amount of oil in a deposit is by inference from geophysical logs. This can only be accomplished after correlation between core analysis and geophysical logs has been established. This can be a cost effective and reliable method but must be used with caution because many geological variables can affect the geophysical response.

HYDROLOGICAL DATA

In addition to information on the geology of the oil sand deposit, information on the hydrology of the deposit and the surrounding area is essential to the design of a surface mining operation. There are several reasons for obtaining hydrological information, including the need for water in the process plant, the possible presence of unwanted water in the mining area, the possible effect of groundwater on slope stability, and the possible effect of mining and processing on the water resources of the area.

The first step in obtaining information on the hydrology is a data search of the surface and groundwater conditions in the area. This information may be available from government agencies or from oil and water wells in the area of the development. Another important source of information on hydrology is the geology of the deposit. At the same time that information on the general geology is gathered to characterize the oil sand resource, information on possible aquifers within the stratigraphic section can be obtained. Once information on the general hydrologic nature of the sediments and on potential aquifers is obtained, more detailed information can then be obtained during the exploration drilling phase of the project.

The same drill holes that are used to obtain information on oil sand grade and thickness can be used to obtain information on the groundwater hydrology. During the rotary or core drilling programs, areas where water loss occurs should be noted because this loss indicates a permeable zone. These zones should be correlated with the geologic information on aquifers. During the exploration planning phase, one should identify the number of holes that will be needed as groundwater observation holes. These usually range from 20 to 60% of the exploration holes. These holes should be drilled without significant drilling additives, or if one must use mud additives, they should be of the biodegradable type. This will allow information on water quality to be obtained

that will not be biased by drilling mud additives. Once the holes are identified, the specific aquifer to be tested in each hole should also be identified. Generally only one aquifer per hole is tested. If problems occur during the exploration drilling that require the use of non-biodegradable mud additives, the observation wells can then be changed to alternative locations.

While the drill rig is still on the site of a test well permeability tests can be run to isolate the zones that are to be tested as potential aquifers. Also known as a packer test this involves sealing off a hole at a given test zone and pumping water into the zone to determine its permeability. Once the permeable zones are identified, one in each given test hole, a screen and plastic pipe can be inserted to allow water from this test zone to enter the pipe and be tested for quality. The test zone is sealed below and above to prevent contamination from any other aquifers.

If a significant aquifer is identified and that aquifer has to be dewatered before mining or is needed for water supply, a pump test should be planned. This involves drilling a new hole, usually larger than the exploration holes, to allow for a nominal 152.4-mm (6-in.) casing and pump capable of producing a few hundred gallons per minute. Observation wells should be established near this test well. If possible these wells should be the same wells established from the exploration drilling. The test well is then pumped to determine the yield of a given aquifer and the level of water in the surrounding observation wells is observed periodically during the tests to determine the drawdown of that particular aquifer. A test well should be put in for each significant aquifer from which either dewatering or water production is anticipated. The observation wells will be left in place and monitored at least once a year throughout the life of the mine and can also be used for testing the quality of the water before and during the mining operation.

GEOTECHNICAL DATA

Geotechnical information is essential to the planning of any surface mining operation. This information includes data on rock strength and characterization of the discontinuities such as faults, fractures, or bedding planes within the oil sand and surrounding rocks.

In open pit planning, geotechnical information is necessary to select the proper mining equipment and design the pit slopes. For instance, if a rock is very hard, it would not be suited for bucket-wheel excavators or draglines without first blasting the material.

A geotechnical study for an oil sand project is usually undertaken by a geotechnical group with specific expertise in this area. The first information that must be gathered is the geology of the deposit and its surrounding rocks. Separate units within the oil sand and overlying rocks should be identified for strength testing. Once the separate, identifiable units are recognized, samples for strength tests can be taken during the exploration drilling. These samples should be of unsplit core and be two to three times the core diameter in length. The tests to be performed on these samples should include a uniaxial compressive strength and triaxial shear test to determine the intact rock strength. The strength tests should be performed in at least two directions, parallel and perpendicular to the bedding.

Other important data characterizing the setting of an oil sand deposit include rock mass discontinuities such as the joints, faults, and bedding planes within a deposit. The techniques for obtaining data on these features include geologic mapping and fracture mapping where surface exposures are

available and collection of Rock Quality Determination (RQD) data from drill core.

SUMMARY

Tar sands deposits constitute a hydrocarbon resource that far exceeds the world's resources of conventional oil. The most economical means of exploiting the near surface part of this resource is through surface mining. The exploration techniques described in this section should provide the information on the grade and geometry of the deposit as well

as the hydrological and geotechnical conditions that are necessary to plan a successful tar sands surface mine.

2.9 Oil Shale Exploration and Geology

R. W. ELAYER
I. P. DORLING
P. W. MCKIE

INTRODUCTION

Oil shale, long known as a potential source of energy, is found in many countries. The largest known deposits occur in the United States, primarily in Colorado, Utah, and Wyoming.

Even though numerous occurrences of oil shale are known, interest in their development has been, until recently, insufficient to support the thorough exploration and appraisal of known deposits or to encourage the search for additional deposits. However, during the past few years, a great deal of oil shale exploration and assessment work has been performed in the western United States, Australia, Morocco, and Brazil, with a view to commercial development.

In the past, oil shale has been commercially mined and used directly as a fuel, or processed into liquid fuels, in many parts of the world including Scotland, France, Sweden, South Africa, Australia, the Soviet Union, China, Brazil, and the United States. At the present time (1985), oil shale is being commercially mined and processed in only two countries. In the Soviet Union, (Estonia), oil shale is used directly as a fuel to generate electricity, and in the People's Republic of China (Fushun and Maoning), oil shale is used to produce liquid fuel and gas. Large open pit oil shale projects have been planned in Brazil, Morocco, and Australia while development of a commercial sized underground oil shale mining and processing operation is already underway in Colorado.

Definition of Oil Shale

Oil shale, in a strict sense, is a misnomer, since it does not contain oil and it is not necessarily a shale, as defined geologically. According to ASTM (1985), oil shale can be defined as a sedimentary rock containing insoluble organic matter that upon heating yields an oil similar to petroleum. Shale oil is the organic liquid obtained from the retorting of oil shale.

Oil shales are diverse in composition, lithologic association and genesis, and range in color from light shades of brown, green or red to dark brown, gray or black. Claystone, marlstone, siltstone, impure limestone, and black shale most often contain enough insoluble organic material to be classified as oil shale. Three general categories of oil shale are known: carbonate-rich shale; siliceous shale; and cannel or coaly shale.

Individual deposits of oil shale yield shale oil in greatly varying amounts. Some yield more than 38 L (10 gal) of shale oil per ton and others yield more than 380 L (100 gal) of shale oil per ton.

World Occurrence of Oil Shale

The world occurrences, geology, and resources of oil shale are well documented by Duncan and Swanson (1965). Oil shale deposits are found in every continent of the world, however, information on their quality, thickness, and extent is varied. The principal known deposits throughout the world are shown in Fig. 1.

The most important and largest known oil shale deposits

of the world are found in the western United States. These deposits are located in Colorado, Utah, and Wyoming, and comprise some of the highest grade resources known. Other important deposits in the United States are found in Indiana, Kentucky, Illinois, Iowa, Michigan, Montana, Nevada, New York, Ohio, Oklahoma, Tennessee, Texas, and Alaska.

Many organic-rich shale deposits are known to exist in Canada, although little data are available concerning them. One of the most important Canadian resources is found in New Brunswick. Other deposits occur in Newfoundland, Nova Scotia, the Northwest Territories, Ontario, Quebec, and the Yukon.

Potentially large deposits of oil shale are known to exist in South America, particularly in Brazil. Smaller deposits are also known to occur in Argentina, Chile and Uruguay. Several large deposits of oil shale occur in Africa, notably in South Africa, Morocco, and Zaire. The Moroccans have been actively working on development of their Timahdit and Tarfaya deposits.

In Asia, the largest and most extensive known oil shale deposits are found in the People's Republic of China and the Soviet Union. About 180 "commercial" oil shale deposits occur in China, distributed in 21 provinces (Duncan and Swanson, 1965). The most important resources are located in Manchuria, Heilongjiang, Kwantung, and Sinkiang provinces. Many deposits of oil shale are reported in Siberia, particularly in Kazakhstan, Kuznetsk, and in northeast Siberia.

Elsewhere throughout Asia, rich but small deposits of oil shale are located in western Thailand, eastern Burma, and northwest Turkey. Extensive deposits also exist in Israel, Jordan, and Syria. Many small, high-grade oil shale deposits are found in Australia and New Zealand. In particular, oil shale is widely distributed in New South Wales, Queensland, and Tasmania.

The oil shale deposits of Europe are extensive and widely distributed. Some of the most important occur in Scotland and Estonia, France, Spain, Sweden, Austria, Bulgaria, Czechoslovakia, Italy, Germany, Switzerland, Yugoslavia, and Portugal. Detailed data are available concerning many European oil shale occurrences, particularly about those in Scotland, France, Estonia, Spain, and Sweden, which have been commercially developed during the past 130 years.

Oil Shale Geology

The world's known oil shale deposits range in age from Cambrian to Recent. The oldest deposits include those found in northern Europe, northern Asia, and east-central North America, while some of the youngest are found in the Green River formation of the western United States, and in China.

Three major depositional environments in which oil shale was formed have been identified. These are large lakes (lacustrine environment); shallow seas (continental platform or shelf environment); and small lakes, streams, and lagoons (coal-forming swamp environment). In these environments, oil shale was deposited from water containing a prolific quantity of flora and fauna, in conditions that precluded oxidation

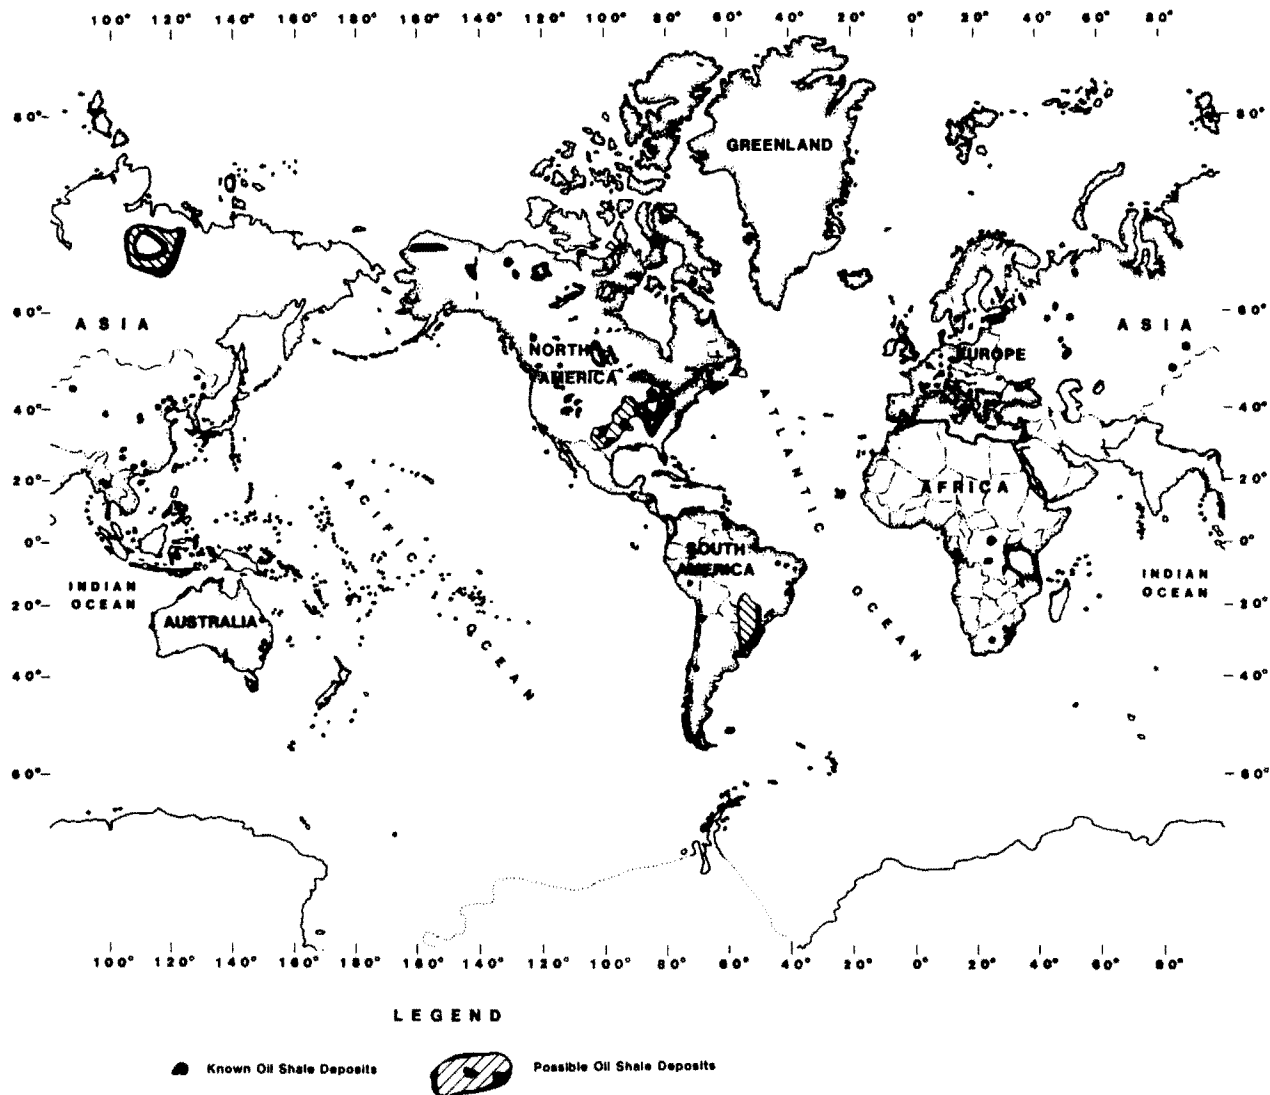

Fig. 1. Principal known deposits of oil shale throughout the world (Duncan and Swanson, 1965).

of the organic material which accumulated on the bottom of the depositional structures.

Oil shales formed in a large lacustrine environment include, most importantly, those of the Green River formation (Eocene in age) found in Colorado, Utah, and Wyoming; the Paraiba River Valley deposit (Pliocene) of southern Brazil; the Albert Shale (Mississippian) of New Brunswick, Canada; and the Aleksinac deposit in Yugoslavia. Such deposits form some of the highest grade, thickest, and most extensive oil shale resources in the world. They are predominantly calcareous and often interspersed with volcanic tuffs, clastic sediments, and carbonate rocks.

Those oil shale deposits which were formed in a shallow sea or continental platform/shelf environment, include the marine black shales of northern Siberia and northern Europe (Cambrian); the high-grade kukersite deposits (Ordovician) of Estonia; the Devonian black shales of the eastern and central United States; the Permian shales of Brazil, Uruguay and Argentina; and the Jurassic black shales of Europe and eastern Asia. These deposits are predominantly siliceous in

character and extend over large areas. They are associated with limestone, chert, sandstone, and phosphatic nodules.

Oil shales which were formed in small lakes and found associated with coal-bearing rocks include the thick, extensive, and high-grade deposits of Fushun (Tertiary) in Manchuria, China and those of late Carboniferous age in Kazakhstan in the Soviet Union. These deposits overlie, or are associated with, coal seams.

Oil Shale Resources

Duncan and Swanson (1965) compiled an order-of-magnitude estimate of the world's oil shale resources (see Table 1). Since this estimate was compiled, considerable work has been performed on oil shale deposits in many areas of the world. Known oil shale resources in Australia and Brazil, for example, have been considerably increased due to recent exploration.

EXPLORATION PHASES

Exploration for oil shale involves the initial "discovery," as well as the geologic work required to adequately char-

Table 1. Known World Resources of Shale Oil

Continents	Billion bbl			
	Proven	Probable	Possible	Hypothetical
Africa	10	90	ne*	534,000
Asia	20	84	3,702	697,400

acterize a deposit for engineering planning. Once a viable deposit is confirmed and operation starts, development geology begins. The main thrust in development geology is geologic control for exploitation.

Exploration geology should not be approached as a cook book exercise. Every oil shale property, deposit, or region has its own particular geologic, physical, and economic characteristics that require one or more modifications to standard exploration practice. The exploration techniques presented here are most applicable to the oil shale deposits of the Green River formation located in Colorado, Utah, and Wyoming.

These techniques, with some possible modification, are applicable to oil shale deposits of the eastern United States, as well as those throughout the world.

The most important consideration in exploration is to identify and characterize a deposit at a minimum cost and in the shortest possible time. To accomplish this, a well organized and phased approach is necessary. This phased geological exploration effort, integrated with engineering studies and intermediate decision points, results in an efficient, well organized program. A flow diagram showing the three main phases of exploration is given in Fig. 2.

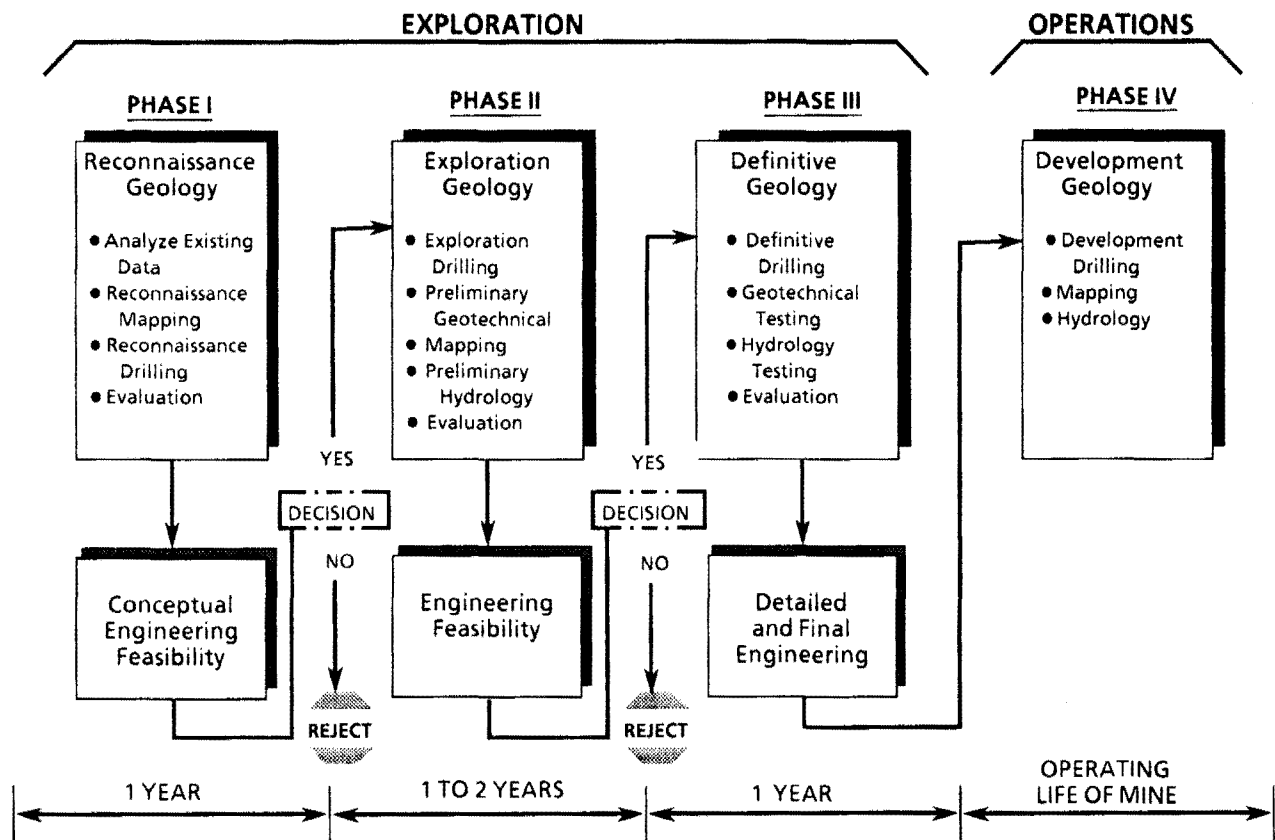

Fig. 2. Flow diagram showing the main phases of an oil shale exploration program, followed by development geology during operations

Reconnaissance Geology—Phase I

The reconnaissance geology phase represents the initial examination of a property or properties to identify tracts or areas having the best potential for acquisition and development. During this phase of work, existing data is collected and analyzed, aerial and ground reconnaissance geology mapping completed, and reconnaissance drilling performed. All information derived from this work is evaluated to determine the best potential areas for more detailed exploration.

The engineering effort which normally follows this phase of work is a conceptual engineering feasibility study. The quality of this study depends to a large extent upon the quality and completeness of the geologic data obtained during the reconnaissance phase. Following the initial exploration and engineering work, a decision can be made either to reject the area or property, or to move on to the next phase of exploration. The time usually required for this phase of work is one year, but less time may be needed if more initial data is available.

Exploration Geology—Phase II

During the exploration geology phase, more detailed and site specific data is acquired to better define the geology for feasibility engineering. This phase involves additional drilling, preliminary geotechnical testing, geologic mapping, preliminary hydrology testing, and geologic evaluation. This phase may last one or two years, depending upon the size of the property under investigation and the amount of drilling required.

The data obtained during this phase may be used in performing a feasibility study that would more accurately define the mining potential of the project. The exploration geology phase and feasibility engineering usually provide sufficient information to evaluate the feasibility of the project so that a decision can be made whether or not to proceed.

Definitive Geology—Phase III

The definitive geology phase is directed at better defining the immediate area of the mine and to gather very site specific data for detailed and final mine engineering. This phase includes drilling, geotechnical testing, hydrological testing, and a geologic evaluation, and is normally completed in one year.

Following this phase of work, the geologic data base should be sufficient for detailed final mine design engineering and construction, which may take several years to complete.

Development Geology—Phase IV

During the operating life of a mine, continued geological work is needed for grade control, structural control and to better define, in advance of mining, the hydrological and geotechnical characteristics of the strata.

EXPLORATION TECHNIQUES

The techniques of oil shale exploration may vary in particular cases, but will often include many things in common. The actual techniques used will depend upon the circumstances of the case. The techniques of oil shale exploration described below are commonly used in the Piceance Creek and Uinta basins of Colorado and Utah. Most of these techniques are also applicable to other oil shale deposits of the world.

Information Review

An important initial step in an exploration program is to compile and review all available and existing information. This information may be in the form of raw data, such as assay reports, or it may be reduced data which has been

synthesized from the raw data. Reduced data, such as oil yield maps, are by far the easiest to work with, but for a reliable evaluation, all available information must be considered. It must be remembered, however, that with the passing of time, procedures and techniques are improved and popular theories are modified to reflect new technology. Existing information, therefore, must be viewed subjectively.

A bibliography is included in the reference section of this chapter that lists some of the many published sources of information on oil shale in the United States. This list is not all inclusive but is representative of the most commonly used sources. Since 1917, the US Geological Survey, US Bureau of Mines, Energy Research and Development Administration, Department of Energy, and several state geological survey offices have added to the available oil shale data base. Most information developed by private industry is confidential, and is not commonly available.

Information on international oil shale deposits usually can be obtained from the government geological agency in the country of interest. In former colonial countries, additional information may be available from government agencies in the mother country. Considerable geologic work is also performed in overseas countries by the US Geological Survey, the United Nations, and other world agencies.

Mapping

Good maps are necessary for performing any detailed geological or engineering work on a property. Topographic base maps are required for recording and presenting geologic information, and for engineering planning and design. Photogeologic maps should be prepared early in the reconnaissance phase. More detailed maps are required in the later phases of exploration.

Topographic Mapping: For reconnaissance exploration, the standard 1:24,000 scale USGS topographic maps are usually satisfactory. These maps can be effectively photoenlarged up to four times to a scale of 1:6,000. The smaller scale 1:62,500 USGS topographic maps can be enlarged effectively about five times to 1:12,000 scale. These maps, however, are not of the quality and accuracy needed for feasibility engineering, exploration, and definitive geology.

For more accurate maps, the area of interest should be mapped using photogrammetric techniques. Maps, at a scale of 1:12,000 or 1:6,000, with contour intervals of 6 m (20 ft), can be prepared from aerial photographs and are satisfactory for most geological work. Maps that are generally used for engineering studies, however, are usually of larger scales, such as 1:6,000 to 1:1,200 for particular areas of concern. When mapping is carried out, a base datum elevation should be specified, which is an average elevation within the mining area, so that the greatest accuracy in data location control and volumetric calculations can be achieved.

Photogeologic Mapping: Aerial photography is a valuable tool for examining and evaluating large areas of land rapidly. The amount of detail varies with the scale at which the photographs are taken. Most government aerial photographs are developed at a scale of 1:50,000 that renders them useful only for reconnaissance work. High altitude U-2 photographs, developed at a scale of about 1:120,000, are also available, as are enhanced satellite images. However, since they cover extremely large areas and are not detailed, they are useful only for regional studies of geologic structures.

Good quality, low altitude aerial photographs are commonly taken to cover the area of interest for photogeologic mapping. Photographs should be taken in the late fall or early spring when the deciduous trees are devoid of leaves

and there is no snow on the ground. Overlapping vertical photographs should be taken for stereo viewing. A series of oblique photos should also be taken when there are cliff faces on the property since they do not appear clearly on vertical photographs. For geologic mapping, vertical photographs should be taken at a 1:12,000, or smaller, scale.

Government aerial photographs are produced primarily in black and white, which is adequate for most photogeologic mapping, since gray tonal contrasts and textures can be interpreted. Superior geologic mapping can be produced using color photography because color photographs show the actual color of the ground surface, making interpretations easier and more reliable.

Multispectral Imaging: Multispectral imaging, or remote sensing, from satellites, for example, Landsat, and aircraft has become a very valuable tool in recent years for regional studies as well as evaluations of large properties. The information derived from remote sensing is developed as an image, not as a photograph. An image of the earth's surface is developed by computer processing of digital sensor data. The sensors detect electromagnetic radiation in selected wavelength ranges, most of which are not visible to the human eye. The image is then enhanced by computer and presented in a variety of ways visible to humans. Satellite imagery, especially that from the new Thematic Mapper (TM), has proven to be very useful in the evaluation of structures in oil shale exploration. Computer enhancement of the digital data can be used to show linear structural features. Radar imagery can be used to produce an image of the earth's surface that enhances linear features and is useful for performing structural studies.

Geologic Mapping: A preliminary photogeologic mapping study should be performed prior to any geologic mapping in the field. This will familiarize the field geologist with the project area and provide valuable geologic information that will help in field mapping. When thorough photogeologic mapping is available, the geologist's field time can be significantly reduced and used primarily for confirming the interpretations made from the photographs.

The most reliable method for compiling field data is to use frosted mylar overlays on aerial photographs so that data will not obscure features that may be important keys to underlying structures. Several overlays may be used to differentiate between various data such as structure and lithology. If the photographs are at a scale of about 1:12,000, the data recorded on them can be easily transferred to 1:12,000 scale base maps. Another common technique is to use aerial photographs, enlarged twice, on which mapping data can be directly recorded. Normal stereo pairs of the aerial photos can be used for reference.

Geotechnical Mapping: Another important objective of an exploration geology program is to determine the geotechnical characteristics of the strata. The feasibility of mining an oil shale deposit, by either underground or surface methods, is dependent upon the competency of the rock. Therefore, it is important to start gathering geotechnical data early on in the exploration geology phase.

Much of the information recorded during geologic mapping is also useful for geotechnical evaluation. Normally, however, geotechnical mapping records a great deal more detail about the characteristics of discontinuities, i.e., joints, partings, and faults.

Geotechnical mapping consists principally of area-wide geotechnical data gathering and site specific line mapping. The area-wide effort consists of developing a representation of the geotechnical characteristics of an area. The area is

first surveyed to identify major structural features and regional joint patterns. Extensive data are collected concerning the strike and dip of the strata and of discontinuities such as joints, fractures, and faults. A detailed description is made of the beds, discontinuities, and bedding planes or partings. Data on strike and dip are normally analyzed using rose diagrams, histograms, and stereographic projections. Detailed line mapping presents site specific information on discontinuities. This mapping includes detailed observations of all discontinuities along a traverse section of about 30 m (100 ft) or more in length. Several sections are measured along several orientations to assure a complete investigation of all discontinuities. Detailed line mapping requires good unweathered rock exposures, which can be provided by driving a test adit or making an open cut face.

Drilling Program Planning

A detailed plan for the drilling program is made before any drilling is carried out on a property. Proper planning will ensure a coordinated program so that needed data is gathered in an efficient manner. The objective of the program must be agreed to by all interested parties. Once the program is approved, a geologist can begin program planning, which is closely coordinated with the project's engineering, geotechnical, and hydrological personnel. A well planned program will yield maximum information from each drill hole at a minimum cost.

The exploration drilling program should be supervised by an experienced geologist with a sound background in sedimentary and structural geology. The geologist responsible for the overall program will coordinate all geologic work and logistics. Large programs require several drill rigs, each of which has a geologist assigned to it. Each rig geologist is responsible for logging all the core recovered.

Drill Hole Design: One of the first steps in planning a drilling program is to determine the number of holes required and to show the location of each hole on a map. Only a few holes are required in a reconnaissance exploration geology program (Phase I), that is directed at identifying a potential property for more detailed exploration. However, in a definitive exploration geology program (Phase III) the objective is to accurately define the geology for final mine design. This may require many drill holes. The trend during the complete cycle of exploration geology (Phases I through III) and operations geology (Phase IV), is to increase definition of the geology through tighter drilling control, by increasing the number of drill holes and decreasing the spacing between them.

Drilling during an oil shale reconnaissance program (Phase I) is carried out to verify previous drilling data or gather information on the total stratigraphic oil shale section. During the reconnaissance phase, a minimum number of holes is required, generally with a spacing of up to many kilometers (Fig. 3a). During exploration drilling (Phase II), however, holes are usually spaced several kilometers apart (Fig. 3b), which should provide sufficient data for performing a mining feasibility study to determine the optimum mining area. During a Phase III definitive drilling program, holes are concentrated in the initial mine area, where the hole spacing varies between 1 and 2 km (0.6 to 1.2 miles). This spacing will usually provide the necessary detail for performing final mine design and grade control. Development drilling (Phase IV) is performed ahead of mining (Fig. 3d), during the mining operation where the holes are spaced at much smaller intervals.

Drilling and Coring Methods: Two drilling and coring

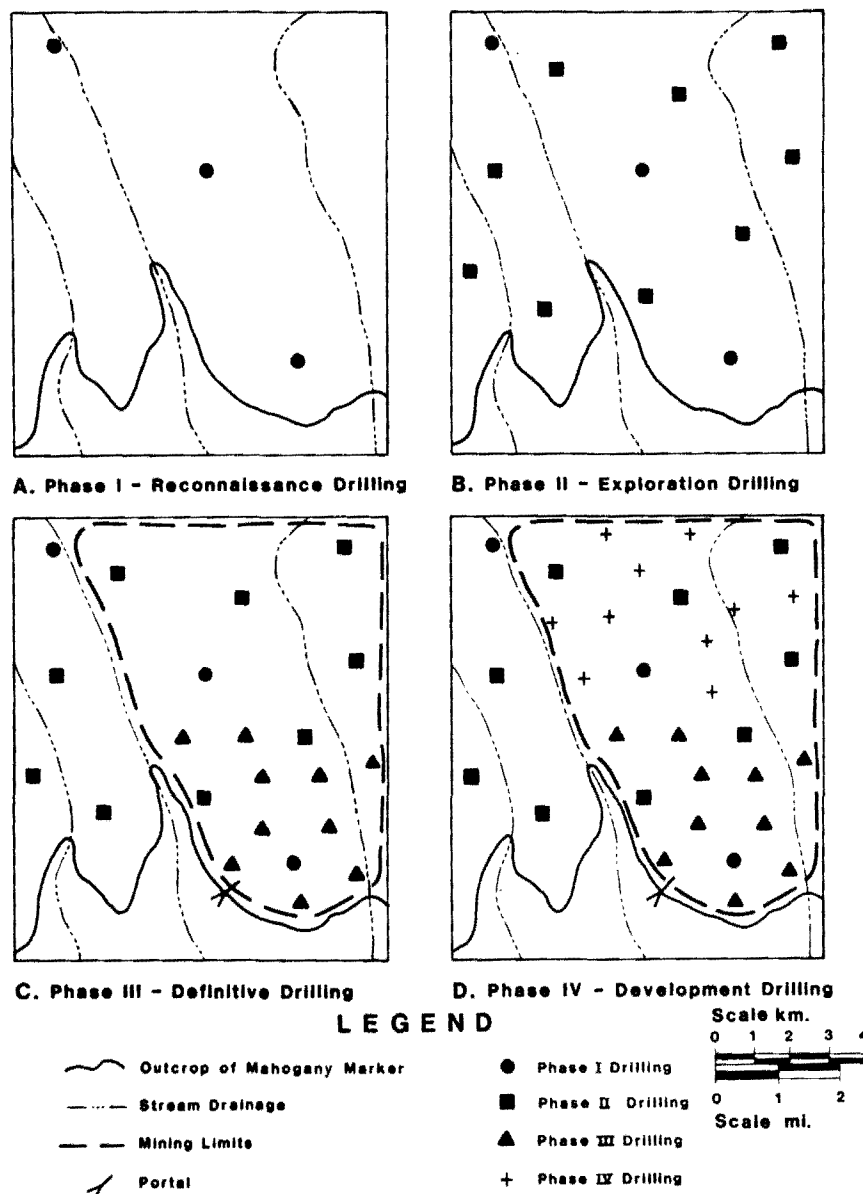

Fig. 3. Phases of drilling in oil shale exploration.

methods are basically applicable to oil shale. In one, a cylindrical rock sample is recovered from the drill hole during the drilling operation (coring), and in the other, cutting samples are recovered during rotary drilling. Usually, oil shale holes are cored from top to bottom, or at least through the main zone of interest. Rotary drilling is not satisfactory when samples are required for grade analysis, and should be used only as a cost efficient, rapid method for penetrating through rock overlying the target zone to be cored.

Diamond drilling is most commonly used for coring. Core drilling is expensive but it is the only method by which good, undisturbed samples can be obtained for assaying, structural geology studies, stratigraphical analysis, and geotechnical testing. Oil shale usually cores very well. Very good core samples of oil shale are normally recovered except through rubblized (due to burning or collapse) and fractured zones.

Two general types of coring tool are available: conventional and wireline. Conventional coring normally comprises a 6.1-m (20-ft) long core barrel that is placed at the bottom of the drill string. Once the barrel is full, the whole drill string is removed from the hole to recover the core from the barrel. The drill string is again lowered into the hole to core the next section of rock. This coring technique is simple but slow, particularly at depths greater than 150 m (500 ft). Progress is particularly slow when conventionally coring through rubblized zones, because the core barrel can become plugged by pieces of oil shale.

Wireline coring is most commonly used in oil shale, whereby core is recovered without pulling the drill string out of the hole after each run. The core is retrieved through the center of the drill string using a cable hoist with a special overshot latching device to attach to the inner core barrel.

Usually, two core barrels are used during coring so that while one is being emptied of core, the other is being filled. The use of two barrels saves time between runs and allows the core to be carefully extracted and prepared for logging.

The size of core to be recovered during a drilling program depends upon the purpose of the sampling program. Most coring operations in oil shale produce conventional NX or wireline NXWL core 5.4 cm (2-1/8 in.) and 4.76 cm (1-7/8 in.) in diameter, respectively. Core samples of either size are large enough for geotechnical testing and for assaying and are also fairly easy to handle and store neatly in core boxes designed to hold 3.05 m (10 ft) of core.

Conventional 7.35-cm (3-in.) or larger core is normally recovered when larger samples are required for bench-scale testing. Large diameter wireline core drilling, designated PQWL and 8.21 cm (3.35 in.) in diameter, has also been successful in oil shale.

Where a deep hole is to be drilled and continuously cored, and in all reconnaissance drilling, wireline core rigs should be used. These rigs are self-contained with a mud pump and all necessary equipment. Coring rates of over 75 m (250 ft) per 12-hr shift with a good driller can be attained. However, wireline rigs are slow and inefficient for rotary drilling.

Rotary drill rigs are used when short sections are to be cored at depth or when air drilling is desired. These rigs (Fig. 4) are also self-contained with mud pump, water injection pump, and air compressor to meet most requirements. In very deep holes, auxiliary air compressors and boosters are commonly used. Rotary drilling is accomplished using a tricone roller bit. A good driller can rotary drill over 152 m (500 ft) in 12 hours. Once the core point is reached, the

tricone bit is replaced with a core barrel and core bit to recover the desired section of rock. Conventional coring rates with a rotary rig are usually about 35 to 50 m (100 to 150 ft) per 12-hr shift at hole depths of about 328 m (1,000 ft). Conventional coring often requires drill collars to add weight for increased penetration.

Core drilling is usually conducted using water as the drilling fluid, but drilling muds are added when needed to retain circulation. In many cases, however, the addition of drilling muds is insufficient to restore circulation when lost, and consequently drilling is carried out *blind*. Blind drilling can be safely accomplished providing sufficient water is pumped down the hole and penetration is slowed down to assure a clean, cool bit. This can be performed by a good driller without sacrificing core recovery or creating bad hole conditions.

Drilling with air is necessary if any drill holes are to be used later for hydrological monitoring or testing. The air compressor units found on most rotary drill rigs provide sufficient air when drilling shallow holes. However, supplementary air compressors and boosters are required for deeper holes, especially when large quantities of water are encountered. Air drilling is most suitable when coring conventionally because of the large volumes of air required. Wireline coring can be performed using air, but the annulus restrictions resulting from the larger-sized drill steel required for the method prevent a sufficient volume of air from reaching the bit in deep holes.

Permitting: The appropriate permits and approvals must be obtained before any drilling starts, whether the property is private, leased, or government-owned, to ensure that no

Fig. 4. Rotary drill rig wireline coring oil shale in Colorado.

violations of the law occur and that no needless damage is caused to the environment or natural resources. It is also advisable to establish early on in a program a rapport with the federal, state, and local government agencies and private land owners in the area of investigation. This will help assure a successful field program, and any future geological engineering, construction, and mining operations.

Logistics: Logistics include all those functions required to support a drilling operation. Adequate prior planning for logistics will assure a much smoother operation in the field and minimize lost time.

Accommodation is needed for the drilling and geology crews. It may be necessary to set up a field camp, depending upon the distance to a town with adequate accommodation. This maximizes the available daily work time. Normally, a drilling crew and geologists can work 12 hours per day if supported by a comfortable camp nearby. Work periods usually last for 10 days, followed by a four-day break.

A communications system should be established early on in a project. Radio-telephones are most appropriate. Through relay systems, radio-telephones have a tremendous range and can easily be integrated with the normal telephone network. When several drill rigs are operating to complete a program, it is advisable to maintain contact between rig geologists by the use of hand-held, two-way radios.

One important logistical consideration is the availability of water for drilling. Core drilling can consume significant amounts of water so adequate sources near the operation must be located and developed. Long water hauls are costly and require additional water trucks and holding tanks to avoid drilling delays.

Geological and Geotechnical Logging

During a drilling operation, samples recovered from each hole must be logged. This is usually performed by the geologist assigned to the drill rig. The samples may consist of cuttings recovered from a drill hole or core samples. Cuttings from a non-cored drill hole are normally collected periodically and segregated into piles representing 1.5 m (5 ft) of drill depth. Each pile is then examined by the geologist, who takes random samples, washes them to remove any drilling mud residue, and then describes their lithology. This logging is carried out at the drill site as the cuttings are recovered, so that the geologist remains fully aware of the drilling progress and can make timely decisions if the projected drilling depths need to be changed.

In a coring operation, the core barrel is first placed on sawhorses next to a core tray when it is recovered from the drill hole. Extracting the core from the barrel is accomplished in various ways depending upon the type of barrel used. A split-tube barrel is by far the easiest to clear. The top half of the inner barrel is removed, exposing the core. The lower half of the barrel is then laid in the core trough and carefully rotated so that the core gently rolls into it. The trough is usually V-shaped, made of steel or wood, is slightly longer than the core tube, and supported by sturdy, steel sawhorses. If a solid core barrel is used, the barrel must be elevated at one end so that the core will slide out of the bottom. However, care must be taken to assure that the core pieces are not dropped or misplaced as they emerge from the barrel. Another technique that is often used with much success requires air pressure to force the core out. A close-fitting piston is inserted into the top end of the core barrel which is sealed with a cap containing an air connection. Air pressure is slowly applied and the core is slowly pushed out of the barrel.

Invariably, the bottom of the core run is tightly held in the keeper spring and may need to be broken out with a hammer.

After the core has been cleared from the barrel, it is first cleaned with a scrub brush and water, then pieced together to determine its original length. Continuous lengths of oil shale core are often recovered, but frequently the core is rubblized so that it is very difficult to reassemble into its original form. In such a case, an estimate of its original length is made based on the quantity of material recovered. Lost core sections must be identified as best as possible and marked with a labeled slab of wood. The core is then marked with stripes along its entire length with broad, felt tip pens to permanently identify the orientation of the core. Normally, the right side of the core, looking at it as if it was standing in the hole, is shown in red and the left is indicated by blue. After *striping*, the depths are marked and labeled on the core with a broad black felt tip pen.

Core samples should be logged, wrapped, and boxed as soon as possible after recovery from the hole. This will minimize the chance for misplacing core sections. It is preferable to log the core while it is lying in the core tray before boxing it (Fig. 5). A typical form for logging is shown in Fig. 6. Each core run is logged on separate sheets. Space is provided for entering all data on the core including Rock Quality Designation (RQD) for geotechnical characterization. Also,

Fig. 5. Field geologist logging core before it is wrapped and boxed.

DRILL/CORE LOG

Fig. 6. Typical logging form used in oil shale exploration.

a cover sheet is completed showing the location, stratigraphic points, and other important information about each drill hole. It is important to note all information derived from logging so that there is a complete record of each hole.

After logging and before boxing the core, geotechnical samples are taken. These samples are usually wrapped in aluminum foil and dipped in paraffin wax to preserve the integrity of the sample. A wooden spacer is left in place of the geotechnical sample so that it can be returned to the core box after testing.

The method for placing the core in the storage box should be consistent. Normally, the core is placed so that the red stripe on the core is to the right, the top of the core section is in the upper left-hand corner of the box, and the core bottom is in the lower right-hand corner. With this method, the core boxes can be placed side by side to view large sections of the core.

Normally, Colorado oil shale cores are not wrapped for preservation during storage, but, to prevent any degradation from affecting test results, all samples and tests should be taken and completed soon after recovery. In cases where the oil shale oxidizes rapidly, the cores may be protected by wrapping in plastic core tubes or, in extreme cases, wrapped in aluminum foil and dipped in paraffin.

Geophysical Logging

Down-the-hole geophysical logging is commonly used in the oil, gas, and nonmetallic minerals industries, and has

proven to be valuable in the geologic evaluation of oil shale. In geophysical logging a sonde is lowered into a bore hole by means of a cable. As the sonde is raised in the hole, it detects specific physical, electrical, and radioactive characteristics of the wall rock and bore hole. This information is transmitted to recording and processing equipment located on the surface. The resulting geophysical log provides a permanent, accurate, and detailed record of the bore hole.

The basic suite of geophysical logs normally used in an oil shale exploration program includes gamma-ray, caliper, gamma-ray density, and non-focused resistivity. These logs provide the geologist with additional valuable information for stratigraphic correlation, as well as an indication of lithology and oil shale grade, that cannot be derived by the logging of core or cutting samples alone.

A portion of a typical geophysical log, developed for an oil shale section in the Piceance Creek basin, Colorado, is shown in Fig. 7. On the far left is the natural gamma-ray curve, which exhibits the natural gamma radioactivity of the rock, measured in API units. This curve is useful for delineating sandstone and shale in the overburden, and tuff and barren marlstone beds in the oil shale. Barren marlstone and shale typically show values greater than 200 API. Oil shale, regardless of grade, exhibits values from about 80 to 120 API. Prominent tuff beds, such as the Wavy Tuff and Mahogany Marker beds in the Piceance Creek basin, will typically show values slightly higher than the surrounding oil shale. The sandstone in the overburden shows values from

Fig. 7. Geophysical logs for an oil shale section from the Piceance Creek Basin, Colorado.

80 to 120 API with cleaner sands showing values below 40 API.

A caliper log is shown as the second curve from the left (Fig. 7). This curve shows variations in hole diameter and reveals important features such as vugs. It is useful for correlating vug zones and must be considered when evaluating other logs, such as density and natural gamma logs, that are dependent upon hole size. The caliper log is generated using a mechanical arm that detects irregularities in the hole wall.

The third curve from the left is a density curve, which has proven to be one of the most useful curves in the geophysical logging of oil shale. This log basically measures the electron density of the rocks encountered in a bore hole by bombarding them with gamma rays from a radiation source, and measuring the back scatter. The emitted gamma rays collide with the electrons in the rock, causing a back scatter and decrease of energy referred to as the Compton effect. The amount of back scatter is related to the electron density which is, in turn, related to the true bulk density of the rock (a function of grain density, porosity, and density of fluids filling the pore spaces).

The bulk density of oil shale is related to its grade. Generally, as the grade increases, its density decreases. The density curve, therefore, indirectly reflects the relative grade of

the oil shale. This relationship has prompted many workers to explore the possibilities of accurately identifying the grade of oil shale from geophysical logs, thus eliminating much of the extensive, costly core drilling required to develop a property.

A field geologist can use the density log to accurately identify high-grade beds and low-grade markers. In the example presented in Figure 7 from the Piceance Creek Basin of Colorado, the high-grade Mahogany Ledge is clearly visible on the density log as a low-density, high-grade unit. Likewise, the lean A-Groove, B-Groove, and other lean zones can easily be recognized by their higher density.

The fourth curve shown in Fig. 7 is a resistivity log. It is a measure of the electrical resistance of the fluid contained within the rock unit. Water containing dissolved salts, for example, shows low resistance. Increased resistance reflects increased carbon and decreased pore space. Generally, higher grade oil shale shows high resistivity, which reflects the high carbon content. The leaner oil shales show lower resistivity.

Sampling

Sampling is a key part of an oil shale exploration program since it provides information on grade, quality, and rock characteristics. This information forms much of the found-

dation for future mine engineering studies and for determining the economic viability of a project.

Three techniques of oil shale sampling are commonly used to obtain representative samples: core, channel, and bulk. The techniques chosen in an actual application will depend upon the requirements of the tests to be made on the samples. Core samples are usually satisfactory for grade determination, geotechnical testing, and bench scale process testing. Channel samples are useful for grade determination and bench scale process testing. For pilot plant testing, bulk samples are required.

Core Sampling: One of the primary objectives of a drilling program is to obtain representative core samples of the oil shale section. A vertical, solid core is perhaps the most representative sample obtainable because it provides material for geotechnical testing and assaying and enables accurate geologic control.

After geologic logging has been completed and geotechnical samples have been removed, the core samples are normally sent to a laboratory where they are sawed in half. Sawing is preferred to splitting because of the better, more representative sample it gives. One half of the sample is returned to the core box for storage. The other half is retained for assaying. The core sections that were removed for geotechnical testing are returned for assaying after the testing is complete.

Channel Sampling: Channel samples are commonly collected from surface exposures at right angles to the bedding. Channel sampling provides material for grade determination only. Because of the extreme grade variability of oil shale in the vertical direction, it is extremely important to equally sample all portions of the zone of interest.

When surface exposures are to be sampled, a good site is chosen which is easily accessible and is free of the obvious effects of weathering or other forms of degradation. The surface of the exposure is cleaned with a brush to remove any foreign material. The location of the sample is marked and sampling begun. A channel is cut through the section of oil shale using a hammer and chisel. As pieces are broken out, they are placed in a sample bag. Care should be taken not to lose any pieces and to cut an even channel so that the whole section is equally sampled.

Channel sampling can also be carried out using a small hand-held rock saw. This technique is commonly used where electrical or air hookups are available. The saw is used to cut two parallel kerfs in the oil shale face. The resulting key between the kerfs is then broken out with a hammer and chisel. A careful operator can obtain very good, reproducible results using this technique.

Bulk Sampling: The feasibility of producing oil shale from a deposit must be determined ultimately by bulk sampling during the final phases of an exploration program. Bulk sampling is carried out primarily to validate grade analyses obtained from drill hole samples, to determine that these samples are representative of the deposit under investigation, and to provide a reliable basis for calculating reserves. Bulk sampling will also provide additional information on the geology of the deposit and geotechnical data necessary for developing a mining operation and for pilot plant testing. Bulk sampling must be carefully carried out to produce oil shale samples that are as representative of the to-be-mined characteristics as possible.

An oil shale bulk sampling program involves the extraction of quite large quantities of material, normally by underground mining but occasionally by surface mining. Typically, access is made by either a small-diameter shaft or

an adit, depending on the topography of the deposit under investigation, from which levels and/or crosscuts and ramps are driven into the oil shale.

Any variations in lithology, grade, or rock characteristics indicated by the drill holes will determine the extent of mining, both horizontally and vertically, required to obtain bulk samples.

Before any bulk sampling of an oil shale deposit is carried out, the procedures for collecting and analyzing samples from predetermined locations must be established. This will assure that acceptable correlations can be made with information derived from the drill holes. The procedures for collecting and preparing oil shale samples are based on the ASTM procedures for coal sampling and conform to established industry practices.

Testing

The object of any sampling program is to obtain representative samples on which tests can be made. Grade determination is the most common reason for sampling. Geotechnical and hydrological testing is also conducted on core samples to determine the strength and aquifer characteristics of the rocks in place. Tests for methane are also carried out, especially where an underground mine is envisaged.

Grade Determination: Oil shale grade determinations are conducted on samples using the ASTM standard procedures D3904-85 titled "Oil from Oil Shale (Resource Evaluation by the USBM Fischer Assay Procedure)." This procedure, commonly referred to as the modified Fischer assay procedure, involves the preparation of a representative sample approximately 100 g (3.5 oz) in weight by crushing and splitting the total sample section of core; heating the sample in a special retort according to a carefully controlled time temperature curve; and collecting and measuring the products of the destructive distillation process. Results are expressed in gallons per ton oil grade; water in gallons per ton; weight percent of oil, water, retorted shale, and gas plus loss; oil specific gravity; and coking tendency of retorted shale.

For accurate grade correlation and grade characterization of the mining zone, 0.3-m (1-ft) sections are normally analyzed for grade, at least through the zone of interest. Thicker sections can be analyzed in reconnaissance drilling and in zones other than the zone of interest, but the thicker sections smear the characteristic high- and low-grade markers, making accurate correlation impossible.

Geotechnical Testing: A geotechnical investigation considers not only the characteristics of intact and jointed rock, but also hydrological factors and the overall geological structure of the property under investigation. Factors such as hydrostatic pressure and zones of weakness (faults, shear zones, and dikes) that affect the long-term stability of a mine and related facilities, must be studied in detail so that they can be included in the mine design.

Geotechnical data derived from previous studies, published literature, and field mapping are used extensively in developing the basic geotechnical characteristics of a property. Additional geotechnical information concerning the property is acquired by shallow borings and deep hole drilling, and by testing of soils and rock samples. The purpose of these tests is to determine, more fully, the parameters necessary to carry out stability and foundation analyses for the design of a mine and related facilities.

Normally, a geologic exploration drilling program will be planned to include the collection of geotechnical and hydrological data to minimize drilling costs. Geotechnical

logs are prepared for drill hole cores sampled by a geotechnical engineer. Selected samples are then sent to a laboratory for testing. Analyses of intact, jointed and broken rock samples are performed. Typical geotechnical laboratory procedures carried out for oil shale include the following tests: uniaxial compression, triaxial compression, indirect tension (Brazilian), direct shear, creep, and modulus of rupture.

Tests are also performed on retorted shale samples to determine water content, dry density, specific gravity, compaction, consolidation, and gradation characteristics. The data derived from these tests are used to establish mine design parameters, determine stability criteria, and foundation requirements.

Hydrological Testing: The data required for hydrologic investigations of a property originate from site specific field testing programs. Since the methodologies utilized to obtain subsurface hydrologic data are closely tied to geologic exploration, hydrogeologic studies are often conducted simultaneously with exploration drilling to maximize the use of each hole drilled and equipment available at the site. The intensity of the hydrologic field program is dependent upon the stage of geologic exploration.

The determination of preliminary hydrogeologic conditions is primarily based upon observations made during drilling. The geologist on site should be aware of and record indicators that exhibit potential hydrogeologic properties such as lost circulation, relative moisture content of cuttings (if drilling with air), geologic material suitable for aquifers (sands, gravels, silts), possible confining materials (clay lenses), increase in water production at various depths, and hole stability (caving). Since the majority of oil shale exploration drilling is accompanied by geophysical logging, several of the parameters measured in the logging process provide good preliminary indications of subsurface hydrologic conditions.

As the geologic exploratory program is expanded, a site specific hydrologic testing program can be designed and implemented to identify additional hydrologic properties required for mine planning. Several of the exploration holes may be cased to obtain potentiometric surfaces of individual aquifers. Groundwater gradients, flow rates, and potentiometric heads can then be determined on a preliminary basis.

In order to evaluate an aquifer unit for specific hydraulic properties (transmissivity and storativity) it must be artificially stressed and the subsequent changes measured. Several basic methods are available for this type of testing on a preliminary basis. Packer and Airlift Stem testing involves the use of an uncased hole while Slug and Airline testing is performed in small diameter, cased holes (Lowman, 1972 and Ferris, 1962).

In order to determine the hydraulic characteristics of a property to the degree of confidence needed to assess operational groundwater impacts (for dewatering, etc.), an aquifer testing technique, using a submersible pump (pump testing) and a series of observation wells, is routinely used.

During hydrological testing, samples of the aquifer water should be collected and preserved for laboratory analysis. The results of this analysis will further characterize the hydrologic regime of the property under investigation.

Methane Testing: The US Bureau of Mines has established, by laboratory absorption measurements on samples, that the amount of methane absorbed by oil shale is proportional to pressure and oil yield. The Bureau has also analyzed oil shale cores for their gas content by a direct measurement method. One recent study illustrating the use of this method is presented in Schatzel and others (1987). This publication presented the results of this study on the

methane content of oil shale from the Cathedral Bluffs Mine, located in the Piceance Creek Basin. They found that cores taken from deep locations of an oil shale deposit, far from outcrops, yield more gas than cores taken at or near outcrops. This indicates, taking into account variations of oil yield and other data, that oil shale mines that are both deep and far from an outcrop will emit low levels of methane gas.

Where underground mining of oil shale is being considered, then, it is essential that some testing for methane be carried out, since there is a possibility that methane gas may be liberated from oil shale into the mine creating an explosion hazard.

Methane testing procedures for oil shale were developed originally from those used for determining the methane content of coal seams (Kissel et al., 1973). The procedure for oil shale involves recovering sections of core, sealing the samples in tubes, and monitoring the release of gas over a period of time. Analysis of the test results shows relative yields of methane gas in cubic feet per ton.

Oil shale core samples required for methane testing should be obtained from those holes that theoretically offer the best chance of encountering methane. As the core is recovered from the hole, it should be placed immediately in the tube, sealed, and protected from excessive heat. In the laboratory, the tube containing the core is connected to a gas collection and monitoring apparatus. The collected gas is sampled and analyzed to determine its content. The volume of collected gas will give an indication as to the amount of methane gas which might be expected in an underground mining situation at that site. After the test is complete, the core is removed, logged, and sampled for assay.

Geologic Evaluation

The purpose of a geological evaluation is to review and interpret all the available data concerning the property under investigation and to present a thorough description of the geologic model that is interpreted from the data. All sources of information and data should be documented.

An important part of the geologic evaluation is presentation of the data and interpretations of maps and cross sections. Maps commonly produced in a geologic evaluation of oil shale include surface geologic maps; surface structure and lineament maps; subsurface structure maps, isopach maps, isograde maps, and oil yield maps which show oil yields in barrels per thousand acres and are commonly used for resource estimation.

Computers are very effectively used for geologic evaluations, since they are excellent for manipulating data, identifying average grades for sections, and identifying zones meeting certain grade and thickness criteria. Computer graphics also aid in developing maps and subsequent volumetric calculations such as resource estimations.

2.10 Industrial Minerals

RICHARD H. OLSON, EDWIN H. BENTZEN, III, AND GORDON C. PRESLEY, EDITORS

1. Asbestos*

Asbestos is the generic name given to a group of fibrous mineral silicates found in nature. They are all incombustible and can be separated by mechanical means into fibers of various lengths and cross sections, but each differs in chemical composition from the others. The commercial grades of asbestos consist of a spectrum of lengths and sizes and are not definitive as are most organic fibers.

It is generally recognized that there are two main groups of asbestos. The first only contains the fibrous serpentine called chrysotile and comprises about 94% of the world production of asbestos. The second group contains five minerals in the amphibole series—crocidolite, amosite, anthophyllite, tremolite, and actinolite. The latter two have no commercial importance.

GEOLOGY

General

Chrysotile constitutes about 94% of the current world production of asbestos and, of this amount, all but a fraction of a percent is derived from deposits whose host rocks are ultrabasic in composition (Berger, 1963; Bates, 1969; Keith and Bain, 1932). This other fraction of the chrysotile production is derived from serpentinized dolomitic limestone. Among the other varieties of asbestos, amosite and crocidolite are found in certain metamorphosed ferruginous sedimentary formations and, together, account for some 5.3% of world production. Tremolite and anthophyllite make up the balance of the production and are generally found in association with highly metamorphosed ultrabasic rocks.

The bulk of world chrysotile production comes from the USSR and Canada. Southern Africa, including Zimbabwe, Swaziland, and South Africa, is the third largest producer with the balance coming from other parts of the world.

Of the Canadian production, by far the greatest amount comes from the Eastern Townships of Quebec with northern British Columbia, Ungava, Newfoundland, and Ontario contributing the balance. Russian production comes mainly from the Bazhenovo district in the central Urals, the Dzhetygara area of northwest Kazakhstan, the Kiembay area in the southern Urals and from Ak-Dovurak near the Yenesei River west of Lake Baikal.

The age of asbestos deposits varies greatly from earliest Precambrian in Zimbabwe and Swaziland to Upper Jurassic in California. The Ontario, Ungava, and Brazil deposits are all Precambrian, while those of the Eastern Townships, Vermont, and Newfoundland are all ascribed a Mid-Paleozoic age, associated with early folding in the Appalachian Mountain belt. The deposits of western Canada are connected with mountain building in the Late Paleozoic while the Russian deposits vary from Early Paleozoic to Late Paleozoic or Triassic in age.

*Excerpt from Mann, E.L., 1983, "Asbestos," *Industrial Minerals and Rocks*, 5th ed., Vol. 1, S.J. Lefond, ed., AIME, New York, pp. 435-484.

Structures

General deformation in the form of faulting, folding, or shearing evidently plays a major role in the localizing of asbestos deposits (Cooke, 1937). The introduction of swarms of small intrusive dikes of acidic to intermediate composition also contributes to the general fracturing and opening up of the rock which, in turn, leads to serpentinization and the formation of chrysotile fiber.

The majority of chrysotile ore deposits tend to occur in serpentinized peridotite rather than dunitic host material. This is probably due to the fact that serpentinized dunite bodies tend to flow when subjected to stress, thereby aiding in the development of fracturing in the surrounding more brittle peridotite.

Asbestos Veining

Chrysotile asbestos is referred to as cross fiber where the fibers lie transverse to the vein, and as slip fiber where the fiber lies in the plane of the vein (Gold, 1967; Cooke, 1937). In the case of cross fiber, the orientation may be anywhere from normal to sharply inclined to the vein walls, in which case it can be referred to as oblique fiber. The fiber in the veins may be straight, gently curved, or contorted. Fiber containing sharp flexures is apt to break easily.

The quality of the fiber ranges from soft and silky to harsh; from highly flexible to brittle; and from strong to weak.

Partings are often present in the veins, either as microscopic discontinuities or as irregular shaped inclusions composed of picrolite, serpentine, brucite, and magnetite, or combinations of these. The veins may be relatively persistent or short and lenticular, occurring in the form of stockworks or in parallel systems known as ribbon fiber. They may be fissure fillings, replacements, or stress-relief features, and are often the result of a combination of these processes.

Some very short fiber is derived from a variety referred to as "mass" fiber. Mass fiber consists of either the complete replacement of most of the original mineral constituents to fiber, each grain of which has a different fiber orientation, or a dense network of fine reticulating replacement veins. Both varieties result in a very high content of short fiber and the rock, which appears to be largely fibrous, is sometimes referred to as "fur" rock.

Other varieties of mass fiber include "platy" fiber, of which the Coalinga deposit is unique. A similar, but less important, variety is known as "mountain leather."

WORLD ASBESTOS DEPOSITS

North America

Canada: *Eastern Townships, Quebec*—Chrysotile asbestos was discovered in two localities in the Eastern Townships in 1878 and has been actively mined at Thetford Mines and Asbestos for over 100 years. The chrysotile deposits of Quebec's Eastern Townships occur intermittently along a major serpentine belt which arcs northeastward into the Gaspé

Peninsula in one direction and southward into the Appalachian Mountain belt of Vermont in the other.

The area yields over 80% of Canada's fiber production and some 30% of the world total, thereby vying closely with the Bazhenovo district of the Soviet Union for first place in world production. Most of the major occurrences are located along a sector 88.5 km (55 miles) long which lies parallel to, and 80.5 km (50 miles) southeast of, the St. Lawrence River extending from a point near East Broughton, 80.5 km (50 miles) south of Quebec City, southwestward past Thetford Mines and Black Lake to Asbestos and Danville which lie approximately 137 km (85 miles) east of Montreal.

This serpentine belt is a typical ophiolitic complex of gabbroic and dioritic rocks, and of pyroxenite, peridotite and dunite, serpentized to various degrees with associated granite, rodingitic, and talc-carbonate rocks. This belt has been described in the past as a partially serpentized ultrabasic intrusive emplaced in the crust along faulted zones of weakness. More recent study would indicate that this giant complex has been extruded onto or just under unconsolidated aluminous and silicious sediments in a eugeosynclinal ocean basin. Magmatic differentiation within the ultramafic magma is thought to be responsible for the formation of the various pyroxenite, peridotite, and dunite phases found in the complex.

The small granitic masses found within the ultramafic complex have been considered intrusive but may be the result of the ingestion and digestion of fragments of underlying sea floor sediments. Subsequent faulting and shearing has resulted in numerous dislocations within and adjacent to the ultramafic complex.

Consideration of this complex as a submarine extrusive simplifies the problems of water for serpentization, allowance for large volume changes, the occurrence of fiber as open fracture fillings in stockworks, and banded fiber in ribbon zones. It also explains the presence of "pillows," usually gradationally serpentized from the surface inward.

The fiber occurs mainly in highly serpentized peridotite (harzburgite containing 10-15% enstatite) and is found in numerous occurrences along the strike of the complex.

There are presently six deposits being mined in the Eastern Townships and numerous others are either dormant or completely mined out. For purposes of description the deposits may be grouped on the basis of their distribution within the belt, i.e., the Pennington dike deposits, those of Thetford Mines area, the Black Lake deposits, and those of Asbestos.

Pennington Dike, Thetford Mines-East Broughton Area (Anon., 1972; Merrill, 1957; Riordon, 1957; Rowbotham, 1970)—Separated from the main Thetford ultrabasic intrusive and extending northeastward for some 27 km (17 miles) or more is the Pennington "dike" which has supported a number of asbestos mining operations, both past and present, over much of its length. This serpentinite body is actually tabular and more sill-like in form, being closely conformable with the country rocks which dip up to 60°SE. Shearing is conspicuous throughout its length. This is interpreted as being a major thrust fault, the plane of which occurs at the base of the sill. Where the sill is narrow, shearing extends from wall to wall and much of the rock is steatized, but the wider portions which reach a thickness of up to 244 m (800 ft) are less affected. It is these wider bulges which contain most of the major ore zones. Slip fiber predominates in all the deposits, though some cross fiber is found in the wider, less sheared sections, particularly toward the southwest.

The narrowness of the ore bodies and the attitude of the sill are obstacles to mining any appreciable depth. Only two

mines, National Asbestos and Carey-Canadian, are presently operating on the Pennington dike.

Thetford Mines Area (Cooke, 1937; Riordon, 1957, 1957a, b; Riordon and Laliberté, 1957)—A large mass of peridotite is host to the Thetford Mines and Black Lake deposits. The Thetford group lies at the northeast end of this mass and contains four closely connected deposits, all of which lie in a well-defined zone along the hanging-wall side of a prominent fault structure marked by the presence of intensive talc-carbonate alteration. The zone has a length of 1.8 km (6000 ft) and a width of 457 m (1500 ft) with the largest and deepest deposits, the King-Bell-Johnson complex, extending to a depth of 457 m (1500 ft) or more. These deep zones are mined by underground methods. The other deposits are the Bennett-Martin, the Beaver-Consolidated, and the Beaver "C." The first two are now exhausted.

A number of subsidiary shears, most of which have dips in the opposite direction to the main fault and strikes that roughly parallel it, tend to break the ore zone into segments. Most of these subsidiary shears are accompanied by numerous bodies of syenite, and evidently developed along the original zones of weakness into which these acid rocks were introduced. Some large bodies of serpentized dunite situated within the ore zone contributed to the fracturing in the surrounding peridotite by behaving as relatively incompetent masses which tended to flow under stress.

Black Lake Area (Anon., 1972; Riordon, 1957a, c, d; Riordon and Laliberté, 1957)—There are three major ore bodies in the general vicinity of Black Lake. The British Canadian-Megantic mine is over 1.6 km (1 mile) long and 0.8 km (0.5 mile) wide, and occupies a position adjacent to a pronounced flexure in the peridotite contact immediately east of the town of Black Lake. This ore body is cut up into ore shoots by a series of roughly parallel shear zones and syenite dikes striking tangentially to the folded contact. Large bodies of serpentized dunite are also found within the ore body and produce low grade to barren sections.

Southwest of the town of Black Lake are the ore bodies which comprise the Lake Asbestos mine, the lake having been drained to permit mining of the deposit beneath. The eastern-most of these ore zones is situated along the hanging-wall side of a northwest-southeast transverse fault which dips to the northeast. Like the major fault in Thetford this zone has also undergone intensive steatization. Another ore body to the west was located beneath a large, flat-lying acid dike which evidently localized the fracturing in its vicinity and no doubt was responsible for the formation of fiber in the vicinity.

The Normandie mine is located about 1.6 km (1 mile) to the west of Lake Asbestos and two miles southwest of the town of Black Lake. This deposit consists of at least three separate ore bodies lying along a northeasterly plunging fold axis which manifests itself in a pronounced Z bend in the peridotite-Caldwell schist contact in the vicinity. The old Vimy Ridge deposit which is now completely worked out is the most southerly of these and occurred close to surface, with much of the upper portions of the ore body truncated and removed by erosion.

The central zone lay completely buried beneath a capping of drift and overburden, and was only discovered by regular grid pattern diamond drilling in the peripheral areas surrounding the old Vimy Ridge mine. The Normandie open pit mine, a very productive operation in its day, has now been mined out.

Further deep drilling on the downdip extension of the Normandie ore body led to the discovery of a deep ore zone

lying well beneath the overfolded capping of Caldwell quartzites. This deposit, the Penhale ore body, has been explored by underground methods and is now being considered for production.

The origin of these three ore bodies is closely related to the folding but may also be dependent on a fault zone trending southwest which parallels the fold axis to the east of the ore bodies.

Whereas the other deposits in the Eastern Townships are made up of a stockwork of asbestos veins, the Normandie, Vimy Ridge, and Penhale ore bodies are composed predominantly of a prominent system of parallel veins of ribbon fiber. These veins form a conjugate pattern but dip predominantly to the northeast with the rake of the ore zone.

The Vimy Ridge and Normandie ore bodies are separated by numerous large syenite dikes and some shearing, whereas the Normandie and Penhale deposits are separated by a zone of low grade to barren material.

Asbestos-Shipton Area (Allen et al., 1957; Bourassa, 1957; Rowbotham, 1970; Riordon and Laliberté, 1957)—The Jeffrey and the now-exhausted Nicolet ore bodies occur along the north and footwall side of a peridotite-dunite intrusive. The Jeffrey deposit, discovered over 100 years ago, has been producing since the early 1880s and is now the largest asbestos mine outside the USSR. The ore body itself has an ellipsoidal to cylindrical or roughly pipelike form, having an average diameter of about 610 m (2000 ft) and its major axis plunging about 55° to the southwest. The ore zone is bounded on both the footwall and hanging-wall contacts by major faults or zones of shearing which dip south-southeast at about 65° to 70°. The ore body is also cut by several irregular shears which trend roughly parallel to the footwall contact and divide the deposit into five major ore zones. Numerous acid dikes of dioritic to syenitic composition tend to follow the shear zones but a few exhibit later cross-cutting tendencies. The fiber is generally of good- to medium-grade cross fiber, though sections of slip fiber and mass fiber also occur.

The Nicolet ore body occurred as a narrow zone along the footwall contact, being bounded on its south side by a prominent zone of shearing. This deposit has now been exhausted.

Baie Verte, Newfoundland—Asbestos is currently mined near Baie Verte (Straw, 1961) on the north shore of Newfoundland. The Advocate ore body forms a continuous fiber zone within the highly serpentinized periphery of a massive elliptical pyroxenite body, 1.6 km (1 mile) long by 0.4 km (0.25) mile wide. The inward dipping fiber zone surrounds the massive pyroxenite core and is in turn surrounded by highly sheared serpentinite. The serpentinite is part of the 88.5-km (55-mile) belt of ultrabasic rocks that separate the schists of the Ordovician Fleur de Lys group from the volcanics to the east.

The massive pyroxenite core shows strong parallel, nearly vertical bands of pyroxene-rich and pyroxene-poor phases, suggesting that it is a fragment of differentiated oceanic crust caught up in a subsequent ultramafic flow. The fiber probably formed in fractures on the highly stressed, highly serpentinized periphery of this peridotite core.

The fiber occurs as a stockwork of good quality fiber veins averaging 6.35 to 7.9 mm ($\frac{1}{4}$ to $\frac{5}{16}$ in.) in length. After mining and milling, the fiber is loaded directly at the nearby terminal for shipment to overseas markets.

Reeves Township, Timmins, Ontario—Chrysotile asbestos occurs at Reeves (Douglas, 1970; Rowbotham, 1970; Hendry and Conn, 1957) 40 miles southwest of Timmins. This de-

posit lies near the northern tip of a large serpentine mass in contact with Precambrian metavolcanics. The south or foot-wall side of the ore body is bordered by a major east-west fault that dips 45°N in the serpentine. Extensive talc-carbonate alteration is common along this fault. Two north-south diabase dikes cut the ore zone. These have caused pronounced alteration of the fiber along their contacts.

The deposit was mined for a number of years but finally closed in 1974 due to marginal grades and pervasive alteration of the fiber.

The deposit in Munro Township in eastern Ontario has long been exhausted by mining. This deposit occurred within a narrow ultrabasic dike bounded by faults containing pronounced talc-carbonate alteration. The ore zone was also offset by cross faulting.

Cassiar, Northern British Columbia—The Cassiar asbestos deposit (Douglas, 1970; Smitheringale, 1957) occurs at an elevation of over 1.8 km (6000 ft) near the peak of Mount McDame in the Cassiar Range. Fiber in the Cassiar deposit is long and of exceptional grade and quality and is associated with an ultrabasic sill intruded into a folded succession of volcanic flows and sediments of Devonian age. The asbestos occurs as cross fiber veins in dark green serpentine commonly 12.7 to 25.4 mm ($\frac{1}{2}$ to 1 in.) wide and up to 4.6 m (15 ft) long. This fiber is shipped in special containers by road to Whitehorse, then by narrow-gauge railway to Skagway and from there by ship to overseas markets.

Clinton Creek, Yukon Territory—Mining of asbestos at Clinton Creek (Douglas, 1970) near the Canada-Alaska boundary was short-lived and the relatively small deposit is now closed.

The deposit lies just south of the Yukon River within 241 km (150 miles) of the Arctic Circle. Here cross fiber averaging close to 6.35 mm ($\frac{1}{4}$ in.) in length occurred in a small ultrabasic body enclosed by phyllites, argillites, and quartzites of Paleozoic age. A portion of the deposit has also undergone strong talc-carbonate alteration. This remote location necessitated costly road, rail, and shipping transportation similar to that of Cassiar asbestos which decreased the margin of profit considerably.

Asbestos Hill, Putunig, Ungava, Quebec—Situated some 64 km (40 miles) from tidewater on Quebec's Hudson Strait (Mann, 1962; Stewart, 1978) on the western margin of a large ultrabasic to basic intrusive, is one of Canada's newest and richest asbestos producers, Asbestos Hill. This deposit, about 762 mm (2500 ft) long and up to 61 m (200 ft) wide, occurs at a point where the dip of the serpentine changes from gently inward-dipping through vertical to steeply outward dipping from the intrusive complex. There is also evidence of a small drag fold where the dip changes most abruptly that appears to form the locus of the ore zone. Talc alteration is present in some zones. The ore is exceptionally high grade with the bulk of the fiber ranging from 4.8 to 11.1 mm ($\frac{3}{16}$ to $\frac{7}{16}$ in.) in length and a minimum amount of short fiber. This produces a good group 4 asbestos-cement fiber. The ore near the surface was, until recently, mined by open pit but the deeper parts are now being considered for development by underground methods. The fiber is partially concentrated at the mine site before being transported to Deception Bay and thence by sea during a 3½ to 4-month shipping season to Nordenham, Germany, for final processing.

Other Potential Deposits—Several other deposits have been considered at various times for possible production. These include the Abitibi deposit situated 80.5 km (50 miles) north of Amos; the McAdam deposit 27 km (17 miles) east

of Chibougamau, both in Quebec; the Lloyd Lake Midlothian Township deposit 64 km (40 miles) south of Timmins, Ont.; and the Garrison deposit 113 km (70 miles) east of Timmins. An attempt was made to develop the Midlothian deposit at Lloyd Lake but the project encountered serious financial problems and was halted.

United States of America: Chrysotile asbestos is mined near Eden, VT, and in two localities in California. Small quantities of chrysotile are also recovered from dolomitic limestones in Arizona.

Pacific Asbestos, Copperopolis, California—The Pacific Asbestos deposit (Leney and Loeb, 1972) is located between Copperopolis and Sonora in the foothills of the Sierras about 201 km (125 miles) east of San Francisco. This deposit occurs within a belt of ultrabasic rocks which trend northwest for 32 km (20 miles) and reach a maximum width of 6 km (4 miles). Strike faulting is common and the peridotites and dunites have been variously altered to serpentine. The ore body occupies a zone about 610 m (2000 ft) wide between two bands of antigorite schist which are believed to represent zones of shearing within the intrusive. Fiber occurs as cross fiber up to 25.4 mm (1 in.) in length but most of the fiber is 6.35 mm ($\frac{1}{4}$ in.) or less. The ore body is cut by narrow dioritic dikes. Talc-carbonate alteration is also prevalent in some portions of the pit.

New Idria-Coalinga, California—The recognition of "platy chrysotile" in the New Idria ultrabasic intrusive led to the successful mining of this fiber in two or three operations northwest of Coalinga (Munro and Reim, 1962) in Fresno County. The ultrabasic body trends northwestward and covers an area some 24 km (15 miles) in length and 5 to 8 km (3 to 5 miles) wide, having been intruded into Jurassic sediments in Late Jurassic or Early Cretaceous times. The intrusive is composed of highly sheared serpentinite characterized by its extremely platy, slickensided nature. "Boulders" of massive serpentinitized material occur scattered through the loose platy serpentinite. There is also evidence of abundant landslide material, a factor which may have contributed to the extreme deformation of the serpentinite.

The ore contains abundant short chrysotile fiber similar to the Canadian variety but low prices and severe safety and health regulations caused the closing of two of the three producers in the area.

Eden, Vermont—The southern extension of the Eastern Townships serpentinite belt of Quebec continues intermittently southward down the Appalachian chain into northern Vermont (Rowbotham, 1970). Fiber occurrences have been known for many years over a considerable area in Lamoille and Orleans Counties. The deposit which has been producing for a number of years lies near the village of Eden. Here a substantial ore body, some 914 m (3000 ft) wide, is being mined at the foot of Mount Belvidere between elevations of 305 and 457 m (1000 and 1500 ft).

Slip fiber is the more predominant variety mined but some good quality cross fiber is also recovered. The host rock is a highly serpentinitized peridotite with the fiber occurring along a contact between gneiss and amphibolite schist.

Mexico: *Cuicatlan, Oaxaca*—A large occurrence of slip fiber has been discovered at Concepcion Papalo east of Cuicatlan, and about 80.5 km (50 miles) north-northwest of Oaxaca in Mexico. The Pegaso occurrence is exposed on two sides of a ridge in highly dissected terrain and appears to be part of a tabular serpentinite body which forms the core of a highly folded and sheared sequence of rocks.

Ciudad Victoria, Tamaulipas—Occurrences of chrysotile fiber are known to occur in the Sierra Madre Oriental Moun-

tains west of Ciudad Victoria (Rowbotham, 1970) in the State of Tamaulipas. These are generally small, discontinuous zones of ribbon fiber and are of little economic significance.

South America

Caná Brava, Goiás, Brazil: The Caná Brava asbestos deposit is located some 193 km (120 miles) north of Brasília and 97 km (60 miles) northeast of Uruaçu in the State of Goiás. Little is known about the deposit except that it occurs in a large ultrabasic body which intrudes gneisses of the Brazilian Precambrian Shield. The ore is apparently a good quality cross fiber of medium length which occurs in two separate zones 549 m (1800 ft) long and roughly 61 m (200 ft) wide. The bulk of this fiber is utilized by local Brazilian manufacturers.

Las Brisas, Antioquia, Colombia: A deposit of chrysotile asbestos is at present being readied for production at Las Brisas, Antioquia, in central Colombia (Harris, 1973). This property lies about 129 km (80 miles) north of Medellín or roughly midway between Bogotá and the Caribbean port of Cartagena. The deposit is reported to comprise at least two separate zones containing fiber of distinctly different grade.

Europe

Balangero, Northern Italy: The bulk of the Italian chrysotile production comes from Balangero (Rowbotham, 1970), a large, low grade slip fiber deposit located near San Vittore about 32 km (20 miles) north-northwest of Turin. The ore zone occurs in a highly sheared serpentinite body about 457 m (1500 ft) wide which trends north-south and is intrusive into paragneisses in the foothills of the Alps in Western Italy.

Zidani, Kozani, Northern Greece: Situated about 121 km (75 miles) southwest of Thessaloniki and 32 km (20 miles) due south of Kozani is a large, low grade slip fiber deposit. The deposit occurs in a highly sheared and fractured serpentinite, probably of dunitic composition which is flanked by crystalline marble to the west.

Troodos, Cyprus: Cyprus (Bear, 1963; Vokes, 1964) is an ancient source of asbestos, as it was known and exploited by the ancient Greeks and Romans. These deposits are some of the largest occurrences of chrysotile in the European area.

Asbestos had been mined for the past 70 years near Amiandos in the Troodos Mountains in the south-southwestern portion of the island. The chrysotile occurs in a body of bastite-serpentinite covering an area some 5.6 km ($3\frac{1}{2}$ miles) north-south and 4 km ($2\frac{1}{2}$ miles) wide, being roughly oval in plan. The best fiber is confined to the southern part of the area near the faulted eastern margin of the peridotite where deformation was most intense. The fiber occurs in small discontinuous lentils or in larger composite veins of cross fiber and picrolite up to 12.7 mm ($\frac{1}{2}$ in.) wide and several feet long. The fiber seldom exceeds 6.35 mm ($\frac{1}{4}$ in.) in length. These deposits are probably Upper Cretaceous in age.

The Troodos mine is at an altitude of 1.5 km (5000 ft) and the crude ore is transported to Limassol by a 30.6 km (19-mile) long aerial ropeway for further processing.

Yugoslavia: Short fiber chrysotile has been produced from a number of mines in Yugoslavia (Rowbotham, 1970) for many years. Deposits are mined at Korlace in Serbia and near Tuzla, Bosnia. Details of the geology of these deposits are not available.

USSR: Russia (Nalivkan, 1960; Rowbotham, 1970; Smirnov, 1971; Stenho and Fronek, 1977; and Petrov and Znamensky, 1978) is now considered to be the largest pro-

ducer of asbestos in the world. The USSR's known reserves are vast and are considered to surpass those of any other country.

There are four major areas of asbestos production in the USSR: the Bazhenovo deposits of the Central and Northern Urals, the Dzhetysay district in the Southern Urals of western Kazakhstan, the newly opened Kiembay district also in the southern Urals and the Ak-Dovurak deposits in Tuva ASSR some 966 km (600 miles) west of the southwest end of Lake Baikal.

Bazhenovo (Bajenovsk) District—According to its production and reserves, the Uralian deposits of Bazhenovo occupy first place in the USSR and rival the Eastern Townships of Quebec for the leading asbestos district of the world. These deposits are affiliated with the Bazhenovo-Alapajevsk or eastern serpentine belt which extends for a distance of about 177 km (110 miles) in the Central Urals. Most of the deposits are centered around the new town of Asbest which is 80.5 km (50 miles) northeast of Sverdlovsk and 1448 km (900 miles) east of Moscow.

The deposits are associated with fault zones in serpentinites which formed predominantly as the result of alteration of peridotites and, to a lesser extent, pyroxenites. Formation of the veins of chrysotile is thought to be by filling of fissures in a massif of ultrabasic rocks.

Mines in the Asbest area and others at Alapajevsk, Novaya and Lesnoje, together with the deposits at Rez (East Aninsk) Krasnouralsk, Lukosk and Krivisk have an annual capacity of at least 1.4 Mt (1.5 million tons) of fiber.

Besides the Bazhenovo group, a number of other deposits of asbestos are known.

Dzhetysay District, Northwest Kazakhstan—This constitutes the second largest area of production in the USSR and has been in production since 1965. The district has a planned annual production of about 726 kt (800,000 tons).

The Dzhetysay district lies some 225 km (140 miles) southwest of Kustanay. Little is known of the geology of the deposits except that they occur in serpentinized peridotites of Early Hercynian (Middle Devonian) age.

Kiembay (Kijembai), Southern Urals—This deposit, the third largest in the USSR, is located some 145 km (90 miles) east of Orsk in the Orenburg Administrative Region. The deposit occurs in a completely serpentinized ultrabasic intrusive. Severe weathering 46 to 61 m (150 to 200 ft) deep has caused the surface fiber to become weaker and relatively brittle.

Ak-Dovurak (Aktovrak), Tuva ASSR—Important deposits of asbestos have recently been developed near Ak-Dovurak, Tuva, near the Yenesei River to the west of Lake Baikal. These deposits are associated with a belt of serpentinized ultrabasic rocks of the Salair complex which forms part of the Lower Hercynian of the eastern Altai-Sayan Province. The ultrabasic intrusions occur intermittently in belts which extend along major faults.

At least six significant deposits have been discovered and the district is reported to contain vast reserves near the village of Kyzyl-Mazalyk and the Kedrovsk deposit 48 km (30 miles) to the south.

Other Deposits—Chrysotile asbestos deposits are known at Molodezhnoje (Molodjezhnoje) some 209 km (130 miles) east of the northern end of Lake Baikal. The deposit is of excellent grade.

The Ilcirsk and Sajan deposits in the same general area also have good potential for future production.

A peculiar fiber deposit is located near Pechenge close to the Norwegian border. Although the deposit is large, the

high iron content is very detrimental to the value and it is doubtful whether the deposit will ever prove to be economic.

Africa

Shabani, Zimbabwe: The Shabani mine (Laubscher, 1964; 1968; Oldham, 1968; Wilson, 1968), situated some 161 km (100 miles) east of Bulawayo, has the largest reserves of fiber in southern Africa. The deposit occurs near the base of a lenticular ultrabasic sill 14.5 km (9 miles) long and 2.4 to 5 km (1½ to 3 miles) wide which intrudes Early Precambrian gneisses. The sill strikes northwest and dips about 40°SW and is composed of dunite at the base, overlain by peridotite, pyroxenite, and gabbro. A swarm of younger diabase dikes cut the ore zone but these are themselves truncated by strong zones of shearing, both parallel and oblique to the basal contact. The intrusion and shearing has caused strong serpentinization of the dunite and heavy talc-carbonate alteration, particularly along the footwall shear zone. The fiber occurs as a stockwork of cross fiber veins described as "stress-controlled dilation seams." The quality is good and the length of the fiber up to 38 mm (1½ in.) in places.

Fiber is also mined at other localities in Zimbabwe, notably in the Mashaba, Belingwe, and Filabusi districts.

Msaui, South Africa: The Msaui mine (Hall, 1930; Pelletier, 1964; Van Biljon, 1964) is located 25¼ km (16 miles) south-southeast of Barberton in the eastern Transvaal and only 9.7 km (6 miles) southwest of the Havelock mine across the Swaziland border. The serpentine in which this ore body occurs is very similar to that of the Havelock deposit in what appears to be the faulted continuation of the same sill-like ultrabasic intrusive. The serpentine body averages 137 m (450 ft) wide and dips about 65° to the east. The best fiber is reported to occur to the north in association with major faulting. The fiber occurs as a stockwork of veins from 0.8 to 19 mm (½ to ¾ in.) and is of the same general high quality as that of Havelock. However, some sections contain a higher percentage of magnetite.

Havelock, Swaziland: The Havelock mine (Pelletier, 1964; Van Biljon, 1964) is located within 0.8 km (½ mile) of Swaziland's western border with the Republic of South Africa, and lies some 19 km (12 miles) south-southeast of Barberton in the eastern Transvaal. Here, a sill-like body of serpentine of the ancient Jamestown Complex is intercalated in the Early Precambrian Fig Tree sedimentary sequence, all of which dip south at 55°. The ore zone has a strike length of 1.5 km (5000 ft) and widths from 18 to 107 m (60 to 350 ft) averaging about 33.5 m (110 ft). The ore body is traversed by a longitudinal fault zone with associated transverse faulting. Talc-carbonate alteration is prevalent in the western portion of the mine. The fiber occurs as a stockwork of high quality cross fiber seams, which average 12.7 mm (½ in.) or more in length and comprise 3% to 4% of the rock. Mining of the upper portion of the ore body was by open cast workings, the deeper portions now being mined by underground methods. The ore is transported by aerial cableway to Barberton for processing.

Other Deposits: Many small deposits of chrysotile asbestos occur at many locations in northern and eastern Transvaal but their combined production has never been appreciable. Most of these are elongated ribbon fiber zones which are in ultrabasic rocks or associated with dolomitic limestones.

Occurrences of chrysotile fiber are also reported from the Ingessana Hills and Qala en Nahl districts of eastern Sudan. Both areas have been explored extensively and several small

deposits have been indicated, but the total potential remains relatively small.

Australia

Woodsreef (Transpacific Asbestos), New South Wales: The Woodsreef (Straw, 1964; Butt, 1978) asbestos deposit is located just east of Barraba approximately 547 km (340 miles) north of Sydney in northeastern New South Wales. The deposit occurs in a lens of serpentinite approximately 8 km (5 miles) long and 2.4 km (1½ miles) wide which forms part of the Great Serpentine Belt of New South Wales. The ore body occurs in a layered peridotite-dunite complex which has intruded sediments of Mid-Paleozoic age, and is approximately 701 m (2300 ft) long and 76 m (250 ft) wide. It is bounded on the western margin by prominent faulting and shearing. Strong shear zones are also prevalent within the fiber zone. The fiber occurs mainly as a stockwork of cross fiber seams and is generally short to medium in length. Although production commenced in 1972, the mine has encountered serious fiber recovery problems and the long-term viability of the deposit is still in question. Most of the fiber is exported to Japan but some is consumed locally.

New Zealand

Pyke Asbestos, South Island: A small occurrence of chrysotile fiber is reported near the headwaters of Pyke River (Babcock, 1978) high in the Southern Alps some 80.5 km (50 miles) northeast of Milford Sound on the South Island of New Zealand. Due to its isolated location and relatively low grade, it is not expected to be exploited in the near future.

Asia

China: Little is known about the geology of Chinese asbestos deposits apart from a few short reports written by various mining and trade delegations (Mamen, 1973). However, various production estimates indicate that China ranks fourth in world production.

The Lai-yüan district of Hopeh, situated approximately 161 km (100 miles) southwest of Beijing, was for many years the only source of chrysotile in China.

Emphasis has recently shifted to the Shihmien area which is located about 402 km (250 miles) west of Chungking in southwest Szechwan (the word *Shihmien* is translated as *rock cotton*). At least a dozen projects now contribute to the production from this area.

A small amount of fiber is also recovered from the Chinchou mine in Liaoning which lies some 426 km (265 miles) east-northeast of Beijing.

India: Indian asbestos production (private communication) is small and includes chrysotile of both ultrabasic and limestone origin, together with some amphibole varieties.

The small Roro deposit, located in southern Bihar State, about 282 km (175 miles) west of Calcutta, is an example of chrysotile production. Here the ribbon fiber occurs in five separate discontinuous zones along highly serpentized peridotite bands and massive to sheared "clot" peridotite. One of these, the Upper Zone, is economic and contains from 7% to 15% fiber over minimum mining widths. The ore is hand-cobbed and sorted for milling.

Japan: Chrysotile asbestos is mined at two localities in the Yamabe district of Hokkaido, Japan (Rowbotham, 1970). The fiber is generally short and all of the production is utilized locally.

CHRYSTILE IN DOLOMITE

In addition to the large deposits of chrysotile asbestos found in serpentized peridotite there are comparatively small tonnages mined from serpentized dolomitic limestones (duToit, 1946; Hall, 1930; Pelletier, 1964; Rowbotham, 1970; Van Biljon, 1964). Such fiber is often of high quality and is free of the magnetite found associated to a varying degree with deposits where the original host rock is of ultrabasic igneous origin.

Chrysotile of this type has been mined from the Carolina district in the Transvaal and in the Salt River and Sierra Ancha regions in Arizona where it is found in narrow bands associated with diabase sills. The only chrysotile of this variety known in the USSR occurs near Aspagash just south of Krasnovask on the Yenesei River.

CROCIDOLITE AND AMOSITE

Both crocidolite and amosite occur in South Africa (Cilliers and Genis, 1964; Cilliers et al., 1964; duToit, 1946; Frankel, 1953; Hall, 1930; Keep, 1961; Pelletier, 1964) in bedded metamorphosed sedimentary formations known as banded ironstones, that may be classed as ferruginous quartzite or probably more exactly as an iron-rich silicified argillite. Cross fiber veins are found as closely spaced ribbons roughly conformable with the bedding which in some localities is distorted and steeply dipping. Crocidolite veins are generally less than 50.8 to 76.2 mm (2 or 3 in.) thick with the bulk of the fiber between 6.35 to 19.05 mm (¼ to ¾ in.) in length. Amosite veins on the other hand often range up to 254 or 305 mm (10 or 12 in.) thick.

Crocidolite is found over a large area of Cape Province occurring in a belt of the Lower Griquatown series of the Transvaal system. One of the oldest producing areas is in the vicinity of Prieska on the Orange River with notable production coming from Westerberg and Koegas, located a few kilometers (miles) down the river. Another producing area of blue asbestos in the Cape Province is farther north in the Kuruman district, and at Pomfret, just south of the Botswana border.

Approximately 322 km (200 miles) southeast of Johannesburg, both crocidolite and amosite are found in similar formations in the vicinity of Pietersburg in northern Transvaal. In some places here, the two varieties have been known to occur side by side in the same vein. Such a vein, having fibers composed of crocidolite at one end and amosite at the other, is referred to as a "doublet." It is interesting to note that there is generally no weakening of the fibrils at the point of contact of the two varieties of fiber.

In the Pietersburg area a quite silky-fibered phase of amosite called *montasite* is found which is often a dusty blue in color and has sometimes been confused with crocidolite.

Widespread occurrences of amosite and crocidolite are known to occur in the Bababudan Hills north of Chikmagalur in Mysore, India. Both varieties of fiber occur in an assemblage of banded ironstones and shales similar to those of northeastern Transvaal but the amosite in particular is noticeably shorter. However, one area of amosite has been intensively investigated for possible production.

Deposits of crocidolite are found in the Hamersley range of Western Australia, as well as in Bolivia and elsewhere.

Amosite-bearing banded ironstone crops out for a distance of over 32 km (20 miles) near Penge in the Lydenburg district of the Transvaal. The fiber-bearing "reef" is being worked at three points along the strike, at Penge, and at the

Weltevreden and the Kromellenboog mines. A good cross section of the country rock has been exposed by diamond drilling to 305 m (1000 ft) in depth. The fiber-bearing banded ironstones and associated sedimentary members dip south-westward at about 20°. This sequence has been intruded by thin persistent sills of dolerite which are conformable with the bedding.

The following column is from a 366-m (1200-ft) diamond drill hole intersecting the fiber-bearing horizon at a depth of 305 m (1000 ft) below the surface at the "Amosa" mine which is part of the Penge property.

Shales
Dolerite sills
Shales
Bevetts conglomerate
Banded ironstone (main fiber zone)
Dolerite sill
Banded ironstone (sometimes fiber-bearing)
Dolomite

The Bevetts conglomerate is considered an important "marker" for the fiber-bearing formation.

In addition to the rock series in the foregoing, diabase cuts vertically across the whole formation at intervals. Evidence as to possible relationship of these dikes to the genesis of the amosite mineralization is inconclusive.

With the steady depletion of known amosite ore reserves, extensive exploration for additional ore was initiated a few years ago. Considerable success was achieved by utilizing a novel structural approach developed by the Cape Asbestos Group.

Careful mapping of the main marker horizons with respect to detailed topographic contours disclosed a system of broad, gentle north-south folds having amplitudes of about 15 m (50 ft) and wavelengths of 1.2 to 1.5 km (4000 to 5000 ft) between crests. A second, superimposed pattern of east-west cross folds was also detected having similar amplitude and a wavelength approaching 2 km (7000 ft). Careful structural mapping further indicated that each of the known or producing deposits was located on the loci of intersections of either anticlinal or synclinal structures. Consequently, by drilling similar loci, at least five new fiber occurrences were discovered and the sixth failed only because the precipitous terrain in the area prevented drilling directly on target. Nevertheless, a drill hole angled toward the target from the nearest accessible location did disclose traces of fiber on the periphery of the target.

This record of successful drilling gives considerable weight to the hypothesis of a structural control for the genesis of amosite fiber. Similar patterns of cross-folding have been noted in many crocidolite deposits in the Northwest Cape and elsewhere.

It should be remembered, however, that the main prerequisite for any fiber development is to have the necessary chemical components for a specific fiber variety. Without the required chemical constituents, no amount of folding, faulting, or alteration can produce any fiber.

It is interesting to consider this structural origin for the genesis of chrysotile fiber as well, because the effects of faulting, folding, and dilation by shearing or intrusion almost invariably occur in close proximity to fiber occurrences.

ANTHOPHYLLITE, TREMOLITE, AND ACTINOLITE

Production of amphibole asbestos (Rowbotham, 1970), other than crocidolite and amosite, includes significant

amounts of anthophyllite, a small quantity of tremolite, and token amounts of fibrous actinolite.

Of the world's known anthophyllite deposits, Finland has been by far the most important producer. However, the famous deposits at Paakkila in the parish of Tuusniemi near Outokumpu in eastern Finland, as well as those of Maljasalmi in Kuusjarvi Parish some 16 km (10 miles) to the east have now been mined out and no further production is anticipated.

The anthophyllite occurred as a series of lenses of amphibolitized and serpentinized ultrabasic material originally thought to be dunitic in composition. These lenses appear to have become detached from larger bodies during an early period of severe deformation. The serpentinized amphibolite lenses occur in a biotite gneiss which is intruded by Late Karelian granites and pegmatite.

The size of these bodies was generally small, varying from 38 to 61 m (125 to 200 ft) in length and 9 to 24 m (30 to 80 ft) in width with a potential of 36 to 91 kt (40,000 to 100,000 tons) of anthophyllite asbestos in each pod.

Exploration for these isolated bodies is difficult and often costly as the area is drift-covered and most of the ore lenses are not exposed at surface.

Present mining of these ore bodies is by open pit with the ore being processed at a centrally located mill.

Other amphibole asbestos is reported from many countries including Yugoslavia, Bulgaria, Brazil, Japan, India, and Taiwan. Little is known of the mode of occurrence of these deposits or their present production status.

A small quantity of anthophyllite is mined near Greenmountain, Yancey County in North Carolina. Production has been small and erratic but is reported to be increasing slightly. Similar material is known to occur in the nearby state of Georgia.

Italy continues to produce a limited quantity of long-fibered tremolite from small deposits located at Val Malenco, in the Sondrio district some 97 km (60 miles) north of Milan. Reports of tremolite fiber are also known from the Aosta district north of Turin in the Italian Alps.

The Mavita anthophyllite mines of Mozambique were closed in 1975.

Although some occurrences of fibrous actinolite are reported, production is extremely limited and of negligible value.

PRINCIPAL DEPOSITS

In the foregoing sections, the major asbestos deposits of the world have been briefly described. Global distribution of these deposits appears to be rather haphazard, but closer examination reveals that their occurrence generally coincides with the earth's major chains of mountain building of all ages. This is particularly true of the Urals, the Appalachians, and Rocky Mountains, but the relationship is more difficult to recognize in Precambrian fold belts.

EXPLORATION AND EVALUATION

The following observations concerning exploration and evaluation apply mainly to chrysotile deposits and to those, in particular, which occur in ultrabasic rocks, and are essentially a review of current methods employed in Canada.

Geophysical

Owing to the lack of outcrop within areas of ultrabasic rocks, or within a belt in which these rocks are expected to occur, both aeromagnetic and ground magnetic surveys (Conn, 1967; Low, 1951) are often employed in the early stage of exploration for asbestos. Ground magnetic surveys

may be used to check and define in more detail anomalies obtained by an airborne survey of a large area, or the ground survey alone may be used for the purpose of exploring a small area.

In the case of an airborne survey, flight lines are normally spaced at 0.4-km ($\frac{1}{4}$ -mile) intervals, and flown as close to 152-m (500-ft) elevation as possible. Where the terrain is rugged, helicopters are used which are capable of maintaining a constant altitude of 91 m (300 ft) above ground level. The spacing between profiles on a ground survey is usually 61 or 91 m (200 or 300 ft) and readings are taken at intervals of 15 or 31 m (50 or 100 ft).

Magnetic surveys are used to locate and define the areas of ultrabasic rocks and, within these, the areas which have been subjected to extensive serpentinization. This is possible because this type of alteration produces a higher content of secondary magnetite. Asbestos deposits in ultrabasic rocks are a result of intensive serpentinization, and for that reason asbestos veining is usually accompanied by a higher concentration of magnetite than is normally found in the barren serpentine. It follows, therefore, that magnetic anomalies obtained over an area of ultrabasic rocks are favorable places to explore for asbestos.

Modern instrumentation has made great strides in recent years, and it is now possible to conduct precise surveys with small lightweight magnetometers, in contrast to the cumbersome equipment used in the past.

Diamond Drilling

Diamond drilling is normally employed to probe beneath the overburden to assess and define the limits of an asbestos deposit. As asbestos ore bodies are usually large in volume, it is customary to drill vertical holes on a grid pattern. In the initial stages of exploration an interval of 122 m (400 ft) and sometimes more may be used, filling in to an interval of 31 m (100 ft) or even less, where an asbestos-bearing zone is encountered. In cases where a deposit is elongated in one direction, holes are generally spaced at closer intervals across the strike. Narrow, tabular targets are best explored by angle holes planned to give the attitude and true thickness of the body.

Care should be exercised to test the area with one or two preliminary drill holes to determine whether the fiber has a preferential vein angle or not. If the angles of the vein intersections appear random, no changes need be made to the program. If, on the other hand, the deposit exhibits prominent vein angles which diverge from the average 45°, then the attitude of all later drill holes should be changed to correct for this variation.

In the past, drill evaluation programs frequently used small diameter, AX [32.5 mm ($1\frac{1}{32}$ in.)] or EX [23.8 mm ($\frac{15}{16}$ in.)], core sizes for evaluating any deposits where shearing was minimal and where holes did not exceed 91 m (300 ft). Experience has shown, however, that large core sizes such as NX [54 mm ($2\frac{1}{8}$ in.)] or BX [41 mm ($1\frac{1}{4}$ in.)], are preferable for better depth penetration, more geologic data, and to aid in fiber logging and dry milling of the core.

Wire-line drill equipment and the use of nonrotating core barrels are also recommended to minimize fiber loss by grinding of the core during drilling.

Steps are taken to recover the sludge only where core recovery is poor, which is generally the case with slip fiber occurrences. Because of the tendency of the fiber to fluff up and remain in suspension, much greater settling tank capacity is required than is the case when recovering sludge from other minerals. Care must also be taken to avoid contami-

nation by grease and vegetable matter as these cannot be burned off without damaging the fiber.

In regions where permafrost conditions are expected, every precaution should be taken to avoid freezing the string of drill rods down the hole. The use of suitable low-freezing drill lubricant media such as a concentrated brine solution is adequate to allow drilling in most areas of permafrost. However, due to the high percentage of fiber cuttings in the water return, the brine solution has to be renewed at frequent intervals—a factor which considerably increases the cost of drilling asbestos prospects in permafrost areas. A number of successful drill ventures under permafrost conditions have been completed, including Asbestos Hill which showed the frozen ground to persist to at least 305 m (1000 ft) below surface.

In areas where drilling is impractical, exposure by trenching or exploration beneath the surface by adit or shaft and lateral workings may offer the only means of assessing a deposit.

Evaluation

The evaluation (Conn and Mann, 1971; Dean and Mann, 1968; Oughtred, 1952) of any asbestos deposit entails the determination of its size, as well as the grade and quality of its fiber. Dimensions of a mineral zone are established by conventional methods, such as mapping, magnetic surveys, trenching, and diamond drilling. The value of the contained asbestos fiber is dependent on numerous physical properties such as fiber length, strength, flexibility, harshness, and color, besides the actual amount of fiber present.

The determination of grade cannot be based on a simple chemical analysis as both the fiber and the wall rock have essentially the same chemical composition. To avoid the complete crushing of the rock and physical separation of the fiber into different lengths, a method of visual evaluation has been developed which requires careful enumeration of the total number of fiber veins, together with the average length of fiber in each vein. These fiber lengths, if expressed in sixteenths of an inch, give an approximation of the grade, each 1.6 mm ($\frac{1}{16}$ in.) vein of fiber in a 1.5-m (5-ft) section being approximately 0.1% fiber.

As the price of fiber varies considerably depending on its length, the use of grade based solely on its percentage fiber content is of little significance. Instead, the product of these two variables, expressed in dollars per ton of rock, offers a far more meaningful value which can be used for direct comparison in the final evaluation.

Drill Core: The method of visual evaluation is ideally suited to the evaluation of drill core.

Each vein of cross fiber is logged and the length carefully measured and recorded in multiples of 1.6 mm ($\frac{1}{16}$ in.). As veins are often of irregular width, the average width of each vein should be estimated. Some veins are of a composite nature carrying partings, or the fiber may have kinks which cause it to break into shorter lengths. The fiber in some veins may be at right angles to the vein walls, in others sharply inclined. Allowance must be made for these conditions in arriving at the true lengths of fiber.

The more precise determination of fiber content calls for the measurement of each vein angle in the core to permit individual volume corrections. However, in practice it is usually assumed that the random angle is 45° and a factor of 1.414 (inverse of the sine of 45°) is used. However, this can be quite misleading if the average angle is rather small, so logging results should be checked against laboratory recovery and bulk sampling wherever possible.

As a rule, the visual reading gives an indicated lower yield of a higher value fiber than a corresponding mill test. This is to be expected as the visual readings disregard fiber lengths of less than 1.6 mm ($\frac{1}{16}$ in.) which are, of course, recovered in milling and are important in grading. Furthermore, a certain amount of pulverized host rock adheres to the fiber, further reducing the grade and increasing the yield by 20% or more. On the other hand, there may be some loss of veins in the core and the veins themselves contain foreign material such as nonfibrous serpentine, picrolite, and magnetite. There is also a tendency, on the one hand, for some breaking of fibers to occur in the mining and milling process while, on the other hand, the fluffed up milled product tends to remain on a screen which an unopened fiber would pass through. For most practical purposes, the discrepancies are compensating and, when a suitable volume correction factor is used, the ore values found by the two methods are generally quite close.

Slip fiber is often associated as a minor constituent in deposits made up mainly of cross fiber, and in others the slip fiber may be the predominant type. It is not easy to determine the slip fiber length by the normal visual methods of logging core; however, its presence may be recorded separately by vein widths and the percentage slip fiber determined in the same manner as used for cross fiber. Laboratory assistance is almost essential in evaluating slip fiber deposits.

Regardless of the method used in evaluating asbestos ore, the final answer should give the value of the fiber, the yield and, from this, the value of the ore in dollars per ton. A bulk sample properly milled and graded readily supplies the answer, whereas a laboratory test normally gives only the yield of an ungraded fiber and, therefore, of unknown value. The visual method, after due allowance for vein angles, gives the yield only and further calculations are required in order to approximate the fiber and ore value.

Face Readings

On the surface or in underground workings, channel sampling may be employed. On the other hand, it is also possible to log these surfaces in a similar manner to that used for drill core. One method is to take a linear reading along either wall of a drift or crosscut and another is to take cross sections at intervals of 1.5 m (5 ft) on the back and both walls to ensure that veins running parallel to the drive are not excluded.

An alternative method is to record all the veins in the face, walls, and back after each round. In order to arrive at a percentage, a factor based on the area involved is applied to the reading for each surface, and an average percentage for the round is determined in this manner.

The fact, however, that the rock tends to break along one or more of the numerous fault planes present rather than across the fault bounded blocks to expose the veins within them, makes it difficult to obtain representative results.

Bulk Sampling

The various methods of logging and sampling outlined seldom give entirely dependable results. The visual methods of logging will usually produce dependable results only where there is a relatively low content of shorts. Slip fiber presents a problem in this connection. Even laboratory results, which are dependent on complete extraction, usually give an appreciably higher fiber value than that obtained in a conventional mill. It is not easy to simulate in a laboratory the conditions to be found at an operating mine where the fiber from the time of blasting to the final product is subjected to

a good deal of handling, some of which is rather severe. The fibers, as a consequence, suffer some breakage in the process.

Bulk sampling is often resorted to as a means to check and to arrive at a suitable factor to be applied to drill core data. This may be done by diamond drilling a block of ground at close intervals prior to mining and milling. The core is then read visually and treated in the laboratory. Provided precautions are taken to avoid contamination and the sample is sufficiently large, results should be reasonably reliable despite the erratic distribution of fiber in the rock.

Tensile Strength

It is important to point out that the measurements made and the evaluations so obtained are based entirely on the length of the fiber which is today a secondary factor in fiber value. Most asbestos-cement fiber grades sold today are valued for the strength they lend to cement or other mixes and a standard scale of Strength Units has been established.

It is imperative then that any evaluation of a chrysotile deposit include Strength Unit evaluations which are laboratory tests involving the testing of an asbestos-cement tile made with the subject fiber. Once the inherent strength of the fiber from a particular ore body has been determined it is usually possible to equate strength to length distribution and dust content measurements.

Tonnage and Grade

To estimate the tonnage and grade of a deposit from diamond drill core data, individual drill holes may be weighted according to their interval using the polygonal method. An alternative procedure is to use cross sections, or groups of cross sections and, by weighting the individual holes in each section, determine the average grade for each section.

A third method employs contoured cross sections, wherein the contouring is based on a reasonable interpolation of the intervening area between drill holes. This method permits the estimator to make use of all available geological information in his interpolation. In open pit operations, contoured horizontal sections may be prepared in this manner to correspond with expected mining level intervals, and these serve as a useful guide to mining. Separate horizontal sections contoured for rock value and fiber value per ton permit the mine operator to produce a more balanced mill feed with respect to both fiber content and grades.

2. Barium and Strontium Minerals

DONALD A. BROBST

ORES AND USES OF BARIUM

The chief ore minerals of barium are barite, the sulfate of barium, and witherite, the carbonate of barium, but barite is the much more common of the two. These ores are sources of barium and its compounds whose many uses are nearly hidden among the technical complexities of modern industrial products and processes.

Most of the barite produced is used in the petroleum industry as a weighting agent in the fluid circulated in drilling oil and gas wells. Barite is used in the manufacture of glass and ground barite is a common filler, extender, and weighting agent in many manufactured products. Barium ceramics have unusual electromechanical properties that make barium titanate useful in the electronics industry. Barium ferrate is used in permanent magnets. Barite is the common feedstock for the production of barium chemicals which have more than 2000 industrial applications in 17 major classifications. Barium metal is used as a "getter" to degasify TV and other vacuum tubes. Barium metal is alloyed with lead and calcium for use in bearings. The specifications of barium mineral products for these many uses generally are set by the user, but some negotiations between producer and user are common.

Barite, also called barytes, cawk, tiff, or heavy spar, has a calculated specific gravity of 4.5, but inclusions of other minerals may reduce this value considerably. Barite in most commercial deposits occurs as irregular masses, concretions, nodules, rosettelike aggregates, and in laminated to massive beds of fine crystallinity. The mineral occurs in many colors, although shades of white to gray and black are most common. The hardness is 2.5 to 3.5 on Mohs' scale (in which the hardness of a fingernail is about 2). Barite is virtually insoluble in water and acid and so is a useful chemically inert material. Thus, the weight, softness, and chemical inertness make it ideal for many of its uses.

Barite is commonly associated with quartz, chert, and jasperoid; calcite, dolomite, siderite, rhodochrosite, and celestite; fluorite; and various sulfide minerals, such as pyrite, chalcopyrite, galena, sphalerite, and their oxidation products. Barite is a common accessory mineral in many types of ore deposits, especially veins that are mined principally for other types of commodities including lead, zinc, gold, silver, fluorite, and rare-earth minerals. Barite is a potential byproduct of many of these and other metallic ore deposits. Barite in vein and residual deposits may contain as much as several percent strontium which substitutes for barium in the atomic lattice of the crystal because of the close similarity of the ionic size of the two metals in their bivalent state. Minor amounts of other metals commonly occur in barite (Brobst, 1958).

Witherite (barium carbonate) has a calculated specific gravity of 4.2 and a hardness of 3 to 3.5 on Mohs' scale. Crystals or complex masses are colorless to milky white or gray or tints of yellow, brown, or green. Witherite is a minor accessory in some barite deposits. In the United States, witherite in commercial amounts has been produced only from a mine at El Portal, Mariposa County, CA, and that operation ceased in 1950. Witherite is a highly desirable feedstock for barium chemical plants because of its solubility in acid.

It seems, however, that witherite constitutes only a small part of the world's barium resources.

Sanbornite, a simple barium silicate, is of potential interest as a source of barium for chemicals. Unlike many silicates, sanbornite is soluble in acid which permits the recovery of barium by further chemical processing. The mineral, long thought to be rare, has been found in abundance with other barium silicate minerals in rocks altered by the effects of heat and pressure from the invading rock materials of the Sierra Nevada batholith in Fresno County, California. The resource potential of sanbornite is virtually unassessed.

Barium occurs in many other minerals, but the concentrations are so low that none is likely to be a potential source of the element in the near future.

The deposits in which barite is abundant enough to recover as the primary commercial product generally are mined in open pits, although there are a few exceptions.

GEOLOGY OF BARITE DEPOSITS

The commercial deposits of barite may be geologically classified by their mode of occurrence into three major types: the vein and cavity-filling deposits, the residual deposits, and the bedded deposits (Brobst, 1958, 1983).

Vein and Cavity-Filling Deposits

Vein and cavity-filling deposits are those in which barite and associated minerals occur along various kinds of fractures, joints, bedding planes, and solution structures such as channels and sink holes that commonly occur in limestones. The vein and cavity-filling deposits commonly have sharp contacts with the enclosing rocks and large-scale replacements of the host rocks beyond the controlling structures are rare. The grade of the ore generally varies within the deposit and from deposit to deposit in a district. Within districts, the deposits are scattered and irregular and range in thickness from a few inches to a few feet and in length from tens to hundreds of feet. Many deposits of the vein-type have been mined by surface methods, but the nature of vein deposits generally means that at some time the mining operation might have to go underground.

Deposits of barite in veins are widely scattered throughout the United States. Many deposits in the western states are associated with igneous rocks of Tertiary age, although notable exceptions are the vein deposits of barite and rare-earth minerals associated with igneous rocks of Precambrian age at Mountain Pass, San Bernardino County, CA (Olson, et al., 1954) and in the Wet Mountains, Custer County, Colorado. In most of the midwestern and eastern states, the association of the deposits with igneous rocks is not obvious.

Barite deposits in solution structures are common in the collapse and sink structures of the midwestern and Appalachian states. These deposits are common in central Missouri where they are known as circle deposits. Many of these deposits have yielded rich ore, but the individual bodies tend to be small. These deposits have been mined by surface methods.

On weathering, vein and cavity-filling deposits may form valuable bodies of residual ore.

The barite and other minerals of the vein and cavity-filling deposits are typical of a suite precipitated from low-

temperature hydrothermal solutions associated with igneous activity. Most geologists agree on such an origin for the vein deposits of the western states. A hydrothermal origin also is suggested for many deposits in the midwestern and eastern states where the mineral-bearing solutions seem to have traveled farther and were somewhat cooler before they formed the deposits. Sawkins (1966) has shown that evidence is accumulating to suggest that some barite and minerals of base metals may form vein deposits from circulating connate and ground waters.

Residual Deposits

Residual deposits occur in unconsolidated material and are formed by weathering from preexisting deposits. Many residual deposits of commercial value in the United States lie within the clayey residuum derived from limestone and dolomite of Cambrian and Ordovician age. Classic examples of these deposits occur in Washington and surrounding counties, Missouri (Brobst and Wagner, 1967; Wharton et al., 1981), and in the Appalachian region from Pennsylvania to Alabama (Brobst and Hobbs, 1968), but especially in the Sweetwater District, Tennessee (Maher, 1970) and the Cartersville district, Georgia (Kesler, 1950).

Most of the residual barite is white and translucent to opaque. It occurs commonly in tabular, fibrous, or dense fine-grained masses, but poorly to well-developed crystals are found. The barite in these deposits ranges from microscopic particles to irregular boulders weighing hundreds of pounds, but most of the masses are 2.5 to 15 cm (1 to 6 in.) in diameter. Chert, jasperoid, and drusy quartz are common in many deposits. Small amounts of pyrite, galena, and sphalerite occur on or in some of the barite, and locally lead and zinc minerals are recovered as a byproduct. Incompletely weathered rock fragments and red to yellow to brown residual clays typically make up the remainder of the deposit. The grade of these ores varies greatly, from less than 10% to 20% barite.

The size and shape of the deposits varies greatly. Some of the larger deposits in Georgia, Missouri, and Tennessee extend over hundreds of acres and are ideally suited to surface mining techniques. The shape of the residual deposit generally reflects the shape of the original deposit. The depth of the deposits depends on the local conditions. Some deposits in Georgia terminate at bedrock at depth of as much as 46 m (150 ft). Many of the deposits in Missouri rest on bedrock that lies only 3 to 5 m (10 to 15 ft) below the surface. These deposits are supremely amenable to mining by surface methods.

The source of the barite is generally thought to be vein material left after the host rock, generally limestone and dolomite, has been dissolved. Connate water and bacteria may play an important part in the redistribution of the barium in the carbonate environment, but their roles are not yet well understood.

Bedded Deposits

The bedded deposits include those in which barite occurs as a principal mineral or cementing agent in stratiform bodies in layered sequences of rocks. Many of these deposits are bedded concentrations of fetid, generally dark gray to black, fine-grained barite. The barite-rich beds have a thickness of less than 2.5 cm (1 in.) to as much as 15 m (50 ft) and contain as much as 50% to 90% barite. The barite beds are interlayered with dark chert, siliceous shale, and siltstone. Some barite-rich zones are more than 30 m (100 ft) thick. Some of these deposits contain millions of tons of barite easily beneficiated for use in drilling fluid and chemical

plants. The structural configuration of the ore bodies and enclosing rocks make many of these deposits amenable to surface mining methods.

Since World War II, bedded deposits have yielded more commercial barite than any other type of deposit, notably in Arkansas, especially near Magnet Cove, Hot Spring County (Scully, 1958); Nevada, especially in the Battle Mountain region, in Eureka, Lander, and Elko counties (Papke, 1984); and near Castella, Shasta County, CA (Weber and Matthews, 1967). Valuable bedded deposits have been mined in West Germany, and more recently in Canada (Boyle and Jambor, 1966) and India (Meelakantam and Roy, 1979). In the last 20 years, extensive bedded deposits have been discovered in the Selwyn Basin, Yukon and Northwest Territories, Canada (Mako and Shanks III, 1984).

Early workers proposed that the barite beds were formed by the replacement of carbonate rocks by barium-bearing hydrothermal solutions from intrusive igneous activity. Many now believe that these deposits are of sedimentary origin and formed virtually at the same time as the enclosing rocks by organic and inorganic chemical processes of concentration and deposition (Miller, et al., 1977).

ORES AND USES OF STRONTIUM

Celestite, the sulfate of strontium, is the chief commercial source of the element strontium and its compounds. Strontianite, the carbonate of strontium, is the only other major strontium-bearing mineral, but it is so rare that it does not enter commercial markets. The principal uses of strontium are in the manufacture of strontium carbonate and nitrate. The carbonate is used principally in the manufacture of glass for TV picture tubes and ceramic ferrites for magnets. The nitrate is used for safety flares and other pyrotechnics where it imparts a brilliant red color to the flame.

The crystals of celestite commonly are tabular and closely resemble those of barite, but the mineral also commonly occurs in fibrous and granular forms. The hardness is 3-3.5 on Mohs' scale and the specific gravity of the purest forms is 3.95 to 3.97. The mineral is usually transparent to translucent, colorless to white, although some material is faintly red or blue.

GEOLOGY OF STRONTIUM DEPOSITS

Deposits of celestite are of the same general types as those of barite, namely, vein, residual, and bedded, with some differences in detail. Most commercial, or potentially commercial, deposits of celestite occur in or near sedimentary rocks as beds or lenses associated with gypsum, anhydrite, or rock salt. Under certain conditions, masses of celestite may be deposited from seawater with anhydrite. Some deposits occur in cavities or veins and disseminated in limestone and dolomite. Disseminations in shales, marls, and sandstones also occur. Celestite also occurs with some metallic ores, such as galena and sphalerite.

The known deposits of celestite in the United States are not currently mined because they are small and not economically competitive with deposits mined abroad. Deposits are described in at least 13 states including Arizona, Arkansas, California, Kentucky, Michigan, Missouri, New York, Ohio, Pennsylvania, Tennessee, Texas, Utah, and Washington (Schreck and Arundale, 1959).

The major deposits now supplying the world's markets are in Spain, where celestite is selectively mined from baritic, gypsiferous host rocks near Granada; Mexico, where the main celestite production comes from lens-shaped bodies concordant with the bedding of limestone host rock of Cre-

taceous age; England, where much celestite has been recovered since the 1880s from residual clays developed over marls of Triassic age in Gloucestershire; Iran, where the celestite occurs in marine sedimentary rocks of Miocene age; and Turkey, from deposits southeast of Sivas.

EXPLORATION TECHNIQUES FOR BARIUM AND STRONTIUM

Highly sophisticated technical methods for prospecting barite and celestite deposits have not been developed, mostly because new deposits have been fairly easy to find in known districts by applying the knowledge of the geologic association and the role of barium and strontium in the various geologic environments in which known deposits occur.

Useful geochemical techniques are available for exploration. A relatively simple and inexpensive turbidimetric test for barium was applied in a region of bedded deposits in western Arkansas (Brobst and Ward, 1965). The results indicated that barium anomalies could be detected that would offer targets for further detailed exploration. Geochemical studies of barium and strontium can be carried out with the use of emission spectrographic and X-ray fluorescence methods, but the equipment is costly. Some commercial laboratories can provide these analytical services. The use of a portable radioisotope fluorescence analyzer in geochemical prospecting for barite and celestite in the west of England has been described by Ball, et al. (1979).

Geophysical techniques of exploration for barite and celestite have not been widely used. Gravity surveys for residual barite deposits were undertaken in Missouri by Uhley and Scharon (1954). They reported differences of up to 35% between the tonnages of barite estimated in the studied tract and that subsequently mined. Klaus and Schroeder (1967) reported that the search by geophysical methods for hidden deposits of barite and fluorite in East Germany yielded less than ideal results. Bose and Vaidyanathan (1979), however, reported considerable success in tracing the large barite deposits in the Cuddapah District, India, by gravity surveys.

LITERATURE

Readers in search of information about barium and strontium, the occurrence and deposits of its ores, and other commercial and scientific aspects of the commodity and the industry will find an extensive literature available, especially in publications of the American Institute of Mining, Metallurgical, and Petroleum Engineers (AIME), the various state geological surveys, US Bureau of Mines, the US Geological Survey, and various technical journals devoted to the mining industry, such as *Industrial Minerals*, *Engineering & Mining Journal*, and *Pit and Quarry*. The literature cited in these various publications will lead readers to much more detailed information. Useful starting points include some general papers and reports by Ampian (1985, 1986, 1988), Dean and Brobst (1955), Brobst (1958, 1970, 1973, 1983), Ferrell (1985), Fulton (1983), Ober (1988), Schreck and Arundale (1959).

3. Borate Exploration

JAMES M. BARKER

INTRODUCTION

Borate minerals have been known and utilized since at least the 5th century when Byzantine artisans used Turkish borax in pottery glazes and as fluxes for precious metal. Beginning in the 13th century, borax from Kashmir, India, and Tibet was brought to Europe. About 1770, sassolite from Italy became the dominant source of borax in Europe and, Italy, along with Germany, produces borate today. Borax was first produced in western South America about 1850 and in the southwestern United States a little later.

Since the 1880s, the playa deposits of the southwestern United States, followed by massively bedded borate and brine deposits in California, have dominated the world market. In addition, the largest known borate reserves were discovered about 1950 in Turkey which is now a close second to the United States in production and the leader in exports. Both Russia and China produce borates today. Chile, Bolivia, Argentina, and Peru intermittently produce borates. Recent major colemanite discoveries have been made in Sonora, Mexico, and borates continue to be found within existing districts in southeastern California.

Kistler and Smith (1983) review the world's borate producing regions and reserves. Barker and Lefond (1985) compiled 18 papers on borate geology, exploration, mining, processing, and end uses. Harben and Bates (1984) summarize the world borate situation.

The unique characteristics of borate derive from boron oxide (B_2O_3). Boron compounds are important in manufacturing applications, particularly in highly industrialized nations such as the United States, members of the European Economic Community, and Japan. The glass-forming properties of borate minerals and refined chemicals account for one-half US consumption of these products, specifically in the manufacture of specialty glasses such as pyrex, frits, and insulation-grade and textile-grade glass fibers. Inorganic chemicals with a borate anion in combination with either a metallic cation, usually sodium, or hydrogen, as in boric acid, display important chemical properties. These are applicable to industries ranging from agriculture to ceramics, to chemical and metallurgical processing to laundry products (Lyday, 1985, p. 91).

BORATE MINERALOGY

Boron-rich minerals vary widely in character due to boron's two coordination numbers, but most are hydrated, low in density, soft, either gray or white, monoclinic or triclinic crystals, and soluble in water and/or acid. Borate characteristics as listed in standard mineralogy texts often differ markedly from those of field occurrences owing to mode of formation, purity, age, or alteration.

At least 150 borate-bearing minerals exist (Table 1) but few are common or commercially important. Dominant industrial borate minerals are borax, kernite, colemanite, ulexite, probertite, priceite, and szaibelyite. Many others, useful as indicators in mineral exploration, occur as minor parts of borate ore bodies, or are mined on a small scale.

Borates are often produced with other commodities such as potash (KCl), soda ash (Na_2CO_3), salt cake (Na_2SO_4), and nahcolite ($NaHCO_3$) in lacustrine or brine deposits.

Other boron deposits may have varied coproducts or by-products, depending on individual deposit characteristics.

BORON CHEMISTRY

Boron always occurs combined in nature. It has properties analogous to carbon, aluminum, and silicon and is concentrated in organic or silicate environments (Reynolds, 1972). Elements of similar character which may be found with boron include lithium, tantalum, cesium, beryllium, uranium, and thorium (Ostroschenko, 1967). Strontium-bearing (celestite) and arsenic-bearing (orpiment and realgar) minerals are common in borate deposits.

Boron is concentrated in residual magma or late magmatic fluids. Boron's large ionic diameter prevents it from easily entering the crystal structure of most silicates, thus making it highly mobile during igneous and metamorphic processes.

Many borate compounds are soluble and ground water and oilfield brines may contain high concentrations of boron. Undissociated boric acid and sodium borate in seawater form a pH-buffer system nearly as important as the carbonate one.

The geochemistry of boron has been documented in less detail than that of most other minor elements (Kemp, 1956). This is primarily due to analytical difficulties related to its low atomic number and close association with silicon and aluminum (Chorlton, 1973; Barsukov, 1961).

BORON DISTRIBUTION

Boron is widespread in nature but usually in trace amounts from which it cannot economically be recovered. Large-scale continental borate accumulation is restricted to evaporite sediments formed in the arid portions of the volcanic-tectonic belts of western North and South America, the eastern Mediterranean, or Asia. Marine accumulations are generally small.

Boron tends to be concentrated in marine sediments by adsorption on clay minerals or by substitution for silicon in clay minerals (Walker, 1975). Potassium-rich clays, such as illite or glauconite, usually contain from 100 to 300 ppm boron in contrast to the seawater concentration of about 4.6 ppm. The boron content of diagenetic or authigenic illite may be directly related to the boron content and salinity of the water in which the illite was altered or formed (Reynolds, 1965). The boron content may be detrital or temperature related. Clastic sediments, both marine and nonmarine, often have a high boron content from detrital tourmaline or illite (Walker, 1963; Shaw and Burgry, 1966).

BORATE MINING

Borates, the major type of boron minerals mined worldwide, are produced using both underground and surface mining techniques along with in situ ones. Surface mining of borates in the USA and Turkey produce the bulk of borates but significant deposits are mined using the other techniques. New underground and in situ mining projects have been implemented or contemplated in the 1980s. Underground mining was the most common form of mining into the 1950s including deposits now surface-mined such as Boron, CA (Obert and Long, 1962). Special situations, such as deposits under Death Valley National Monument, dictated under-

Table 1. Important Boron-Bearing Minerals

Mineral Name	Mineral Composition	Mohs Hardness	Specific Gravity	Crystal System	B ₂ O ₃ , Wt %	Boron, Wt %
Borax	Na ₂ B ₄ O ₇ ·10H ₂ O	2-2 1/2	1.71	Mono.	36.5	11.3

ground borate mining in the 1970s and 1980s (Billie, Boraxo, and Sigma mines) using continuous miners adapted from coal mines. Great depth and low ore grade at the Hector deposit east of Barstow, CA, dictated in situ mining which was not carried past the testing phase.

Geology of Borate Deposits

Commercial borate deposits have formed in five main ways (Table 2): (1) by precipitation from brines in a permanent or semi-permanent shallow lake or a deep lake, (2) as crusts or crystals in mud of playas, (3) by direct precipitation near springs (warm or hot) or fumaroles, (4) by evaporation of marine water, and (5) by crystallization at or near granitic contacts or in veins. The deposits formed by precipitation in permanent shallow lakes are large and produce most of the world's borates. Other occurrences are comparatively small and most are now uneconomic.

Lacustrine Borates

Large-scale borate precipitation in shallow lakes requires that several conditions be met. A source of boron is necessary and is usually a nearby thermal spring, but may be a distant one. Weathering and erosion of preexisting borate deposits or bedrock is usually a secondary source. Rock weathering typically supplies relatively little boron but may be locally important.

Borates have relatively high solubilities so an arid climate helps produce boron supersaturation and retards borate dis-

solution. Nonborate saline minerals and sediment may predominate with most boron in an interstitial brine rather than in borate crystals. An interior drainage system with a relatively small drainage area concentrates boron and minimizes boron dilution by excessive inflow of water, other ions, or sediment.

The borate lake basin must either have at least occasional exterior drainage to remove accumulated brine containing competing ions, or must be stratified with complex brine-evolution mechanisms active. Subsequent diagenesis, remobilization, folding, faulting, and erosion normally alters and complicates the initially simple borate mineralogy and distribution.

The most common borates are those that form at surface or near-surface temperatures and pressures. One sequence in which these borates crystallize has been determined by field and laboratory work. Muessig (1959) summarized these data and found that the most likely primary mineral in each borate group was the highest hydrate (see top four groups, Table 1). The general applicability of these data are open to question because, depending on the activity of water and temperature, other borate mineral hydration levels can be primary (Barker and Barker, 1985). As borate minerals dehydrate during paragenesis, their density and hardness tend to increase along with their boron content. Replacement by calcium carbonate is common for colemanite and similar borates.

A stratified borate-rich lake can develop strong thermal

* L = lake deposit; P = playa deposit; BR = brine; H = thermal spring deposit; M = marine deposit.

† B = borax; C = colemanite; P = probertite; U = ulexite; K = kernite; S = szaibelyite; SS = sassolite; BC = boracite; PR = priceite; H = howlite.

Sources: Kistler and Smith (1983), Watt (1973), Wang (1974, 1975), Evans, et al. (1976), Barker and Lefond (1985).

stratification. A dilute surface layer over a hypersaline borate brine can trap solar energy so efficiently that temperatures exceeding 90°C are reached in these bodies of water called heliothermal lakes (Barker and Barker, 1985). This combination of elevated temperature and low activity of water alters the thermodynamics so that less hydrated borates, such as colemanite, are the stable mineral phase. Colemanite or other low hydrates can be a primary mineral under these conditions.

Playa Deposits

Borates in playas are formed as surface incrustations or crystals within near-surface sedimentary layers. The primary mode of formation is by repeated evaporation of incoming boron-bearing water and by capillary evaporation of ground water. The volume of sediment and other evaporite minerals is normally much greater than the borate volume so the borate crystals are matrix supported. Repeated solution-recrystallization cycles result in massively bedded strata. Playas

may be related to an earlier lacustrine phase, so superimposed lacustrine/playa types are possible.

Thermal Spring and Fumarole Deposits

Thermal springs and fumaroles may emit boron-rich water or gases which precipitate boron-bearing minerals locally due largely to cooling. Such deposits may form proximal spring aprons or crusts of borate with the unprecipitated borate perhaps supplying distal lake or playa environments.

Marine Borate Deposits

Marine borate deposits are generally small. The borates are often a byproduct of mining some other evaporite mineral such as potash (Kuhn, 1962). The borate accumulation is generally an insoluble residue either differentially leached from local marine evaporites or formed diagenetically from them. The largest deposits (such as Inder) may be related to submarine thermal activity or evaporation of seawater with anomalously high boron content (Kistler and Smith, 1983).

Pegmatite Deposits

Boron is usually concentrated in the residual fluids associated with siliceous intrusions (Barsukov and Egorov, 1957). Boron-containing minerals (tourmaline, lepidolite, and others), may crystallize very late in a pegmatite (Ofstedal, 1964) or boron may be mobilized into the country rock or into fluids feeding thermal springs. Boron may also be leached from country rock (particularly marine illite) by boron-poor residual magma or hydrothermal fluids (Ewers, 1977; Ellis and Mahon, 1967).

EXPLORATION FOR BORATES

Geophysical Exploration

Geophysical surveys utilizing gravity, magnetic, nuclear, electromagnetic, resistivity, and seismic methods have been employed for borate exploration. However, no borate deposit has been found using geophysics alone. Geophysical techniques are useful for delineating the shape, structure, or depth of known borate bodies or for solving local geological problems in borate terranes. Several methods discussed subsequently have significant but underutilized potential for locating unknown borate deposits.

Seismic Methods: Colemanite, but also limestone, tend to have seismic velocities greater than surrounding mudstone or shale. Borates often occur stratigraphically near basalt flows or other igneous bodies, both with seismic velocities which may be similar to the high colemanite velocities. These rocks supply, along with an occasional borate deposit, many high-velocity zones so other methods must be utilized to limit the number of exploration targets to a manageable total.

Density Surveys: The average density of borates is usually very near that of the surrounding rocks and sediment. Density contrasts approaching 1:1 are typical. Such small contrasts are not easily discernible using gravity techniques, although this method is useful in determining basement configuration.

Resistivity Surveys: Many borates have high resistivities as dry, single crystals, but field occurrences tend to have ion-rich interstitial water and associated nonborate minerals which mask this characteristic. Caliche deposits often inhibit energy penetration during resistivity studies in arid areas. However, resistivity surveys are a potentially useful, but as yet poorly understood, approach to borate exploration. Preliminary field studies suggest that large ore bodies may have sufficient contrast if the edges are traversed during measurement.

Nuclear Techniques: Boron is a very efficient thermal neutron absorber. It has a very large neutron capture cross section which is hundreds of times greater than other elements common to most borate deposits, especially sedimentary ones. Neutron methods are successful for indicating downhole presence of boron, up to a few hundred ppm, in oilfield brines and hydrocarbons using the neutron lifetime log, and tens of percent in bedded-lacustrine borates using the neutron-neutron log.

Magnetic and Electromagnetic Methods: Neither magnetic nor electromagnetic methods indicate the presence of borates directly. They do indicate details of subsurface geology such as faults, buried basalt, and other features that can lead to borate discoveries or deposit delineation. Paleomagnetic orientation and dating is useful in borate basin analysis and modeling.

Geochemical Exploration

Although it has been tried in Russia (Buyalov and Shuyraylyva, 1961), exploration for borates using geochemistry is

not widespread. Boron has been used in Canada as a pathfinder element in exploration for metallic deposits of tin, lead, zinc, cadmium, gold, silver, tungsten, and others (Boyle, 1971).

Several approaches are possible using the following characteristics of boron: (1) Boron is often associated with elements such as strontium, lithium, tantalum, cesium, and beryllium; these elements have similar chemical properties. (2) Boron is very soluble and may be added to ground water by leaching of sedimentary borates (particularly sodium borates), during igneous and hydrothermal activity, or during metamorphism which characteristically shows a decrease in boron content in rocks with increasing metamorphic grades. (3) Plants require boron for healthy growth, but the concentration range is very critical (Levinson, 1974). Borates are added to both fertilizers and defoliants with slight differences in concentration required to affect the plants either way. Effects depend on the plant species as seen in Death Valley where serophytes grow on or near pure borate outcrops. Plants not adapted to boron stress are easily killed by a few ppm boron. Due to boron's high solubility, plants can be useful indicators of its presence in ground water. False-color infrared imagery in the proper wave length indicates subtle variations in plant chlorophyll, reflectance, etc., and could be used for regional studies. However, desert plants (xerophytes) associated with the arid or semi-arid climate of most borate terranes create a problem. These plants have small and sparse leaves, causing low image density and high-boron tolerance, causing no measurable effect. (4) Heavy mineral analysis, based primarily on detrital tourmaline, can be used in exploration for certain metallic deposits (Gleeson, 1968; Boyle, 1965), or borate-rich pegmatites. (5) Boron concentrations in desert varnish are much higher near borate deposits and in borate terrane in general (Lakin, et al., 1963).

Geological Exploration

Prior to 1970, borate exploration in the United States during this century was infrequent. Modern geological, geophysical, and drilling methods were rarely systematically applied, especially away from producing mines. In other regions, notably Russia in the 1930s and Turkey in the 1950s and 1960s, large borate deposits were found using geology and drilling in borate terranes and over suspected deposits.

Empirical Exploration Guides: A number of empirical exploration guides have proven useful in delineating borate terranes and for locating borates as follows: (1) tectonic belts; (2) dry and hot climate; (3) lacustrine rocks of Cenozoic age; (4) presence of igneous rock, thermal springs, and associated minerals and elements; (5) evaporite deposits, particularly containing borate minerals; (6) borate efflorescences and playas; (7) abundant limestone and brecciation; and (8) arsenic, lithium, and strontium anomalies.

Use of these parameters can rapidly and readily narrow areas of search and thus are valuable tools. Most are empirical guides, so the greater the number appearing in an area, the greater the potential for exploration success there.

Tectonic Belts—Borate ore deposits are usually associated with three main tectonic belts. The smallest deposits are formed at thermal springs and on playas in the Andes Mountains of South America. These are probably indirectly related to subduction along the Chile trench (Norman and Santini, 1985).

The largest borate deposits are in Turkey with smaller deposits in India, China, and Tibet. All are located along the tectonic belts extending from the eastern Mediterranean through the Himalaya Mountains into China.

The large deposits in the southwestern United States and north-central Mexico are related to the extension following overriding of the East Pacific rise by the North America plate. Separating these belts from tectonically similar ones without borates is a dry climate.

Dry and Hot Climate—A dry, hot climate, both at the time of deposition and later, is favorable for borates. High net evaporation helps saturate solutions relative to boron. Boron minerals, particularly sodium borates such as borax, are very soluble and so do not normally crop out under humid climates. The less soluble borates (ulexite, colemanite) are not highly resistant to weathering over geologic time.

Cenozoic Lacustrine Sediments—Most borate deposits are found in nonmarine sediments of Cenozoic age. These sedimentary rocks are of lacustrine origin for the largest deposits. Previously exploited playa or spring deposits are comparatively small while marine borate deposits are both rare and small.

Volcanic Rocks and Thermal Springs—The source of continental boron is generally attributed to volcanic emissions, particularly thermal springs. Areas with Tertiary volcanic rocks and existing thermal springs are favorable. This is so even if they do not now have a high boron content because boron may be supplied to a basin intermittently. However, very hot springs typically have a low boron content compared to warm ones (Barker and Barker, 1985).

Evaporite Minerals—Borates commonly occur without associated evaporite minerals. Large deposits (such as Searles Lake in California) can occur with them and certainly evaporites could be deposited in one part of a basin while borates are deposited in another part. The proximity of commercial borate deposits, most of which are evaporites, is the single most favorable condition in borate exploration. The presence of salt, potash, anhydrite, and gypsum is all favorable although these are often of marine, rather than continental, origin.

Borate Efflorescences and Playa Deposits—Crusts of borates on the surface, or disseminated crystals and aggregates near the surface, may indicate the existence of nearby massive borate deposits. Most of the world's playa deposits are low-grade surface accumulations and consist of ulexite, borax, tincalconite, and other minor borates. The playa borates in Death Valley were known for several years before exploration upstream exposed large, bedded, lacustrine borate outcrops. The Gerstley deposit (a long-active mine) near Shoshone, CA (Barker and Wilson, 1976; Noble, 1926b), was found by exploring behind outcrops which contained very minor radial growths of ulexite in mudstone.

Limestone and Brecciation—Limestone is often associated with borates. In the Death Valley region, the borates are embedded in calcareous shale with limestone abundance increasing near and within the borate body. During evaporation of a brine, both boron and carbonate saturation increases. Carbonates would begin to precipitate before borates and could continue to do so as borates precipitated. Such a mechanism would account for the large amount of limestone in and around lacustrine borate accumulations.

Sodium borates can alter to sodium-calcium or calcium borates by ion exchange or leaching. Leaching and alteration can continue until only limestone remains. The limestone may be pseudomorphous after borate and have a low B_2O_3 content of 1 to 3%. Such a situation in outcrop indicates possible borates at depth (downdip) below the near-surface weathering zone.

The alteration of sodium borates or other borates causes a volume decrease as water of hydration decreases. A result

is the collapse brecciation common within borate deposits and in the surrounding rock. This brecciation is most pronounced above a borate ore zone and decreases away from it.

Arsenic, Lithium, and Strontium—Arsenic-bearing minerals, especially orpiment and realgar, suggest thermal spring activity. Their presence in lacustrine rock is a very favorable association. Both lithium and strontium are high at borate deposits. The lithium is typically in clay minerals such as hectorite or illite. The strontium is celestite, a sulfate, which commonly occurs as overgrowths on borate crystals such as colemanite. Regions with positive lithium or strontium anomalies are highly favorable for borate occurrences.

Field Tests: Four borate tests (Nemodruk and Karalova, 1965) are useful for field determination. These involve a flame test, reaction with turmeric paper, colorimetric determination, or taste.

Flame Test—Some boron minerals yield a yellowish-green flame when heated alone, but the majority require the application of H_2SO_4 or boric acid flux (3 parts $KHSO_4$, 1 part CaF_2). If decomposable by H_2SO_4 , boron compounds burn with a yellowish-green flame [owing to the formation of acid methyl ester $B(OCH_3)_3$] when ignited in an evaporating dish with alcohol and concentrated H_2SO_4 . Borates not decomposable by H_2SO_4 should be mixed with three parts of boracic acid flux and introduced into the flame on a clean platinum wire. A flash of green indicates the liberation of volatile boron fluoride (BF_3).

Turmeric-Paper Test—If turmeric paper is moistened with a dilute HCl solution of boron and dried, it assumes a reddish-brown color. It is then moistened with NH_4OH , and a bluish-black or grayish-blue color results, depending upon the amount of turmeric and boric acid present. It is advisable to run a blank test at all times. Solutions of zirconic, titanic, tantallic, columbic, and molybdic acids also color turmeric paper brown, so this test for boron can be employed only in their absence or with caution. Tantalum and columbium are especially prone to occur with boron due to geochemical similarities.

Colorimetric Test—Add several drops of polyvinyl alcohol (PVA) solution to a drop of iodine solution on a borate sample. The mixed solutions will turn blue if a borate is present. The change to blue is rapid for high boron concentration (over 300 ppm) but may take up to 30 min for 80 ppm. Nonborates may yield confusing colors: $CaCl_2$ is indistinguishable; $NaHCO_3$ is close; and Na_2CO_3 or K_2CO_3 have some particles appearing borate blue but most are purple. $NaCl$, $MgCl_2 \cdot nH_2O$, $BaCl_2$, and Na_2SO_4 (somewhat more blue to neutral), also yield a purple color.

The PVA solution is made by sprinkling 10 g of polyvinyl alcohol (DuPont "Elvanol" No. 7-50 or Braun FH 600) into 900 mL of cold distilled water while stirring vigorously. After a slurry is obtained, heat to about 75°C and continue stirring until the solution clears. Add 100 mL of concentrated HCl.

The iodine solution is made by dissolving 1.2 g of iodine and 3.0 g of KI in a small volume of distilled water, then diluting with 100 mL of water. Take 50 mL of this solution and further dilute to 250 mL to make an 0.02N solution. Store in dark glass bottles to extend shelf life. This reagent loses color after several months and is then ineffective.

Large amounts of organic materials such as acetone, N,N'-dimethyl-formamide, dioxane, ethanol, methanol, formic acid, and pyridine destroy the blue color, while others extract iodine, causing the color to fade.

Taste Test—Soluble borates have a sweetish, astringent taste.

Drilling: The drilling of borate deposits is similar in most respects to that of other evaporites. A drilling program for borates must be designed for a particular project with its unique conditions.

Water is typically acceptable as a drilling fluid for the less-soluble borates but hydrocarbon-based fluids may be necessary for more soluble ones. Care is needed to insure that excessive leaching of cores is avoided. Borate deposits are often vuggy causing lost circulation which can be exacerbated by solution of evaporites within the deposit.

Many borate deposits occur in lacustrine rocks with abundant expansive clay. This leads to excessive swelling by clay hydration. Hole problems result if water loss from the drilling fluid to the clay is not controlled by proper chemical treatment.

SUMMARY

Boron is widespread in nature. Large-scale economical accumulations are restricted to lacustrine sediments or rocks formed in arid portions of the volcanic-tectonic belts of western North America and South America, the eastern Mediterranean, or Asia. Dominant borate mineralization depends on temperature and activity of water. At low temperatures and high activity of water, higher hydrates are favored. At higher temperatures and lower activities of water, such as in a heliothermal lake, lower hydrates are the stable phase.

There are no sure methods for locating borate deposits but there are a number of empirical exploration guides that have proven useful in narrowing the search for borate deposits. These are: (1) tectonic belts; (2) a dry, hot climate; (3) lacustrine Cenozoic rocks; (4) the presence of igneous rocks, thermal springs, and associated minerals and elements; (5) evaporite deposits, particularly if borate minerals are present; (6) borate efflorescences and playas lakes; (7) limestone brecciation; and (8) arsenic, lithium, and strontium anomalies.

The search for new economic deposits of borate minerals requires diligent exploration and imaginative geologic thinking but is exciting and can be financially rewarding.

4. Chromite*

Chromite is the only ore mineral of metallic chromium and chromium compounds and chemicals. Because of this fact, *chromite* and *chrome ore* are used synonymously in trade literature. In commercial market quotations, chrome ore is the term commonly used. Chromite per se, because of properties imparted by its chromium content, is used in refractories and in special purpose molding sands for metal casting. There are many other minerals containing some, generally minor, amounts of chromium, but none are commercial sources of the element (Thayer, 1956).

Under present conditions, the US and North America, with the possible exception of Cuba, have no commercial ore reserves. There are chromite deposits, as will be described, but they would be used only under highly abnormal conditions if all outside sources were cut off for an extended period. All chromite used in the US is imported from the eastern hemisphere in which are contained the principal world reserves. The main suppliers in 1980 were the Republic of South Africa (43%), the USSR (21%), the Philippines (12%), Albania (11%), Turkey (8%), and others (5%). The strategic nature of chromite is obvious.

GEOLOGY AND MINERALOGY

Mineralogy

Chromite is a variety, or more properly stated, a composition range, of the spinel group of minerals (Stevens, 1944; Ulmer, 1970). This range can be expressed as $(\text{Mg}, \text{Fe}^{2+})\text{O} \cdot (\text{Cr}, \text{Al}, \text{Fe}^{3+})_2\text{O}_3$.

The composition also can be generalized as $\text{R}^{2+}\text{O} \cdot \text{R}^{3+}_2\text{O}_3$. Molecular ratio of divalent to trivalent parts theoretically should be, and generally is, close to one. A lower than one ratio usually indicates oxidation of some original FeO to Fe_2O_3 (Stevens, 1944).

Chromite compositions can be represented graphically by a prism of six theoretical end members as shown in Fig 1a. The curved pie-shaped volume within the prism is where the natural chromites occur. Extending this volume down to the FeFe_2O_4 corner may allow for chromium magnetites but chrome ore chromites are all near the $(\text{Mg}, \text{Fe}^{2+})(\text{Cr}, \text{Al})_2\text{O}_4$ side as shown by the shaded area of the mid-plane projection, Fig. 1b. A further idea of composition range is gained from the projection of Fig. 1c. (All diagrams show molecular proportions.) The constituents shown by these diagrams account, in most chromites, for 99+ % of the compositions. But titanium, vanadium, manganese, and nickel are present in traces up to slightly more than 1% in most chromites.

TiO_2 is the most prominent of those accessory oxides and occurs from a few hundredths to about 1%. Reports of TiO_2 of 1.4 to 2.0% may indicate a separate titanium mineral, such as rutile or ilmenite. Unusual Ti-Cr spinels (not ores) have been reported (Cameron and Glover, 1973). Vanadium is seldom analyzed but accounts for around 1/2% (as V_2O_5) in Bushveld chromites (Cameron and Emerson, 1959). In most chromites vanadium amounts to less than 0.1%; MnO and NiO are very persistent constituents and generally each amounts to a few tenths of a percent. The latter three elements can be accommodated into the spinel structure.

Excerpt from Mikami, H.M., 1983, "Chromite," *Industrial Minerals and Rocks*, 5th ed., Vol. 1, S.J. Lefond, ed., AIME, New York, pp. 567-584.

Chromites of economic interest have a Cr_2O_3 content of 25 to about 65%. Predominantly, the Cr_2O_3 of commercial ores ranges from 30 to about 60%. This refers to the chromite mineral free of gangue—which, of course, it never is. The always present interstitial gangue minerals are generally orthopyroxene, olivine, calcic plagioclase and their hydrous alteration products, serpentine, chlorites, and talc. In fact, the hydrous alteration magnesian silicates are probably more commonly present than the original minerals (although they may reveal, by microstructure, the original silicates from

which they were derived). Other less common to rare gangue minerals that have been found in various deposits include dolomite, magnesite, brucite, sepiolite, chrome tourmaline, uvarovite (chrome garnet), kämmererite, quartz, kaolin, pyrite, mica, and goethite. These minerals have been formed by metasomatism. A spectacular, though exceptional, example of this process is the large-scale alteration of original ultramafics to talc-quartz and talc-carbonate host rocks of the Selukwe, Zimbabwe, chromite deposits (Cotterill, 1969).

The geologist, engineer, or industry consumer will practically always be dealing with chrome ores or concentrates that are mixtures of pure chromite and essentially chrome-free silicate gangues. Enrichment of ore in chromium physically can only be accomplished by separating chromite from gangue, but the Cr₂O₃ content will never be higher than that of the chromite. Physical beneficiation methods are the only economical methods of upgrading chrome ore. Chemical methods for removing iron from chromite are known but not practical at present.

Table 1 lists some typical pure chromite analyses accompanied by analyses of the corresponding ores showing the diluent effects of the gangue minerals. SiO₂ and CaO are exclusively contained by the gangue and Cr₂O₃ by the chromite whereas MgO, Al₂O₃, and FeO are distributed in both minerals.

Physically, chromite is generally jet to dark grayish black with luster from shiny vitreous to resinous to dull. Hardness is 5.5 to 6.5 and specific gravity, 4.1 to 4.7. It is brittle, without cleavage, and fractures unevenly with conchoidal tendencies. Some chromites may react weakly to a hand magnet, but most will not. But all can be moved in a strong electromagnetic field.

Chrome ore generally occurs as massive aggregates of chromite grains 0.05 to 30 mm, more commonly 1 to 5 mm, in size. Interstitial gangue in shippable massive ore amounts from as little as 2 or 3% to as much as 25% for very high chromium chromite. The amount of gangue permissible before concentration becomes necessary depends, of course, on the chromite composition. As gangue increases, chrome ore grades from massive to disseminated ore. Gangue in crude

ore in some mining operations can go well beyond 50% if beneficiation economics allow. Chromite grains range from near euhedral octahedrons to anhedral rounded to irregular blocky shapes. Cracks and fractures are common in some deposits. Microbrecciation to mylonitization is prominent in the Selukwe, Zimbabwe, ores (Cotterill, 1969). Lineation, foliation, and series of aligned partings, the so-called "pull-apart" textures, are found in some deposits (Thayer, 1964). Another common texture is nodular ore, also called grape, shot, pebbles, etc. This consists of spherical to ovoid aggregates mostly 5 to 40 mm in diameter. The nodules consist predominantly of chromite grains, generally in the 1 to 5 mm size range, in a silicate (commonly olivine-serpentine) matrix.

In the Transvaal stratiform deposits nodules of a texture and mineralogy somewhat different from those commonly seen in podiform deposits are found (Thayer, 1969). The Transvaal (Bushveld) nodules are spherical to ovoid bodies 5 to 50 mm in diameter. Cameron and Desborough (1969) state:

Each nodule consists of one or more crystals of bronzite or plagioclase poikilitically enclosing abundant fine-grained chromite grains. Nodules are generally set in a matrix of coarser-grained chromite. They are high in silica compared to the matrix material, and portions of certain seams in which nodules are abnormally abundant are unworkable. At certain mines, light crushing of the crude ore disintegrates the matrix material, the nodules are then removed by simple screening, and the ore is correspondingly upgraded.

In podiform deposits, nodules generally are not excessively high in silica and may comprise good ore if sufficiently concentrated in the host rock matrix. For a further description of nodules and orbicules in podiform deposits, see Thayer (1969).

In thin section chromite ranges from dark yellow through orange reds to opaque. Polished sections in vertically reflected light are light to medium gray. Chromite is isometric;

hexoctahedral, in the space group $Fd\bar{3}m$. Unit cell size a ranges continuously from about 8.200Å for high aluminum, low iron and chromium to ~8.330 for high chromium and iron chromites.

Geology

All primary chromites, and this means nearly all presently economic chrome ore deposits, occur in ultramafic rocks or their altered derivatives. The primary ultramafic rocks are peridotite, dunite, and pyroxenite and the principal derived rock is serpentine (properly called serpentinite). Serpentine is, in fact, the most common gangue mineral associated with chromite. Chlorite and talc schists are also alteration products of the primary silicate minerals. The ultramafic rocks are parts of peridotite or pyroxenite-gabbro complexes. Gabbros (including norite) and anorthosite are present near many chromite ore bodies in lesser amounts than the ultramafic rocks. In some chrome ore districts, e.g., Masinloc (Philippines) and Camagüey (Cuba), the ore bodies are found in peridotite near the peridotite-gabbro contact (Stoll, 1958; Davis et al., 1957). Gabbroic rocks occur in some ore bodies as cross-cutting dikes and inclusions. In some districts, e.g., the Bushveld, chrome ores may occur within norite or anorthosite, but mainly they occur in pyroxenite or peridotite.

Types of Deposits

Chrome ore deposits are divided by structural types into two major categories: stratiform and podiform. The *stratiform* deposits, exemplified by the chromite of the Bushveld complex of the Transvaal, are characterized by occurrence as parallel layers of great lateral continuity. In this stratiform class, the ore layers tend to be coextensive with the containing layered rock sequence much as are coal seams within sedimentary formations. The containing rock layers are themselves recognizably persistent, continuous, and extensive so that the occurrence and placement of the ore layers are amenable to conventional geologic mapping methods. Other examples of stratiform deposits are the Great Dyke of Zimbabwe (Worst, 1960); Kemi in Finland (Kahma, et al., 1962); Campo Formoso, Brazil (Thayer, personal communication); the Stillwater Complex, Montana (Jackson, 1964); Fiskenaasset, Greenland (Ghisler and Windley, 1967); and Bird River Complex, Manitoba (Jackson, 1964). The last three named are not economic ore deposits at the present time.

The other major type of chrome ore deposit, which includes all known deposits besides those already named, has been variously designated as sackform, piecemeal, discontinuous, or podiform. Following Wells, et al. (1946) and Thayer (1964), the term *podiform* will be used here. In contrast to the stratiform, the podiform deposits occur as pods, lenses, sackforms, slabs, and all sorts of irregular shapes. The ore bodies may also be tabular and occur in layers, but the important feature that distinguishes this type from the stratiform is that the ore bodies are not continuous, and in many districts follow no recognizable systematic distribution within the containing country rock. In fact, the distribution may be erratic, random, and unpredictable.

As mentioned previously, in some districts ore bodies seem to be concentrated in peridotite near its contact with gabbro, a fact that serves as an exploration guide, but since the designated areas are still very large in proportion to the size of the ore bodies, this criterion cannot locate individual ore bodies. Ore bodies may occur in strings or clusters, but these assemblages may give out without warning. The size of these podiform chrome ore bodies range from a few tons

(depending on economics of mining) to one that contained more than 14 million tons (Coto mine, Philippines). The majority of bodies range from a few tens of thousands to a few hundred thousand tons. Single ore bodies of even one million tons are quite rare, e.g., Gölolan mine, Turkey.

The contacts between massive chromite and country rock may range from very sharp to gradational in single ore bodies. By gradational is meant grading into rock by increasing amount of silicate and corresponding decrease of chromite. If the gradational zone is wide, the practical mining limit defines the boundary of the ore body. In some deposits, ore with high silicate content may be mined as disseminated ore and be subject to beneficiation. Float, or alluvial, chromite may contribute to production in some districts but generally is a minor factor. Such deposits derived from adjacent primary deposits are mined in Zimbabwe and Brazil. During 1980 a small chromite beach sand mine on Palawan Island in the Philippines was started up.

EXPLORATION, PROSPECTING, AND EVALUATION OF RESERVES

The most fundamental basis for searching for chromite is its virtually exclusive occurrence in ultramafic rocks that are, in turn, parts of ultramafic-gabbro complexes. But there are a number of large areas of ultramafic rocks in which no significant chromite ore bodies have ever been found, although there is no known basis for saying that they contain none. The second important point in identifying a chromite deposit as stratiform or podiform. The differences are so dramatic that there should be no confusion between the clearly recognizable stratiform deposits such as the Bushveld, Great Dyke, Stillwater, and Bird River on the one hand, and those presently designate podiform which encompasses most of the rest of the known commercial deposits. These include the Balkans-Asia Minor region, USSR, Zimbabwe exclusive of the Great Dyke, Caribbean, Philippines, India, New Caledonia, Pakistan, Iran, Sudan, and possibly others.

New deposits classified as stratiform in the past two decades are Kemi, Finland (Kahma, 1962); Campo Formoso in Bahia, Brazil (Thayer, personal communication); and Fiskenaasset, Greenland (Ghisler and Windley, 1967). The Brazilian deposit had been thought to be podiform but more detailed mapping has identified it as a sheared-out stratiform traceable for ten miles in heavily weathered terrane.

Prospecting and estimation of reserves in the stratiform complexes are subject to conventional geological field methods because there is a rational genetic basis for explaining and predicting the distribution of the chromite layers. The theory is that the chromite and containing ultramafites originated from a common liquid magma by differentiation and crystal settling or what has been termed *magmatic sedimentation*. Furthermore, these formations have been comparatively little disturbed from their original locations or attitudes. There has been some faulting and tilting, but no replacement. The structural displacements are still generally amenable to solutions by stratigraphic methods. The theory has difficulty in explaining every mineralogical and chemical detail, variation, and nuance found in the deposits, but overall it appears to be the best available and—more importantly for the mining geologist—it works.

The podiform deposits present a drastically different picture. Although the petrogenetic relations between chromite and host rocks appear to be similar, i.e., explainable by differential crystallization from a common magma, their size, shape, and, especially, their spacial arrangement and distribution are completely different from the stratiform. The ore

bodies are separate, discrete, and generally appear to have been thoroughly scrambled. A currently favored theory of podiform origin proposed by Thayer (1969) is that these ore bodies were once layers in stratiform complexes but have since been broken up by tectonic forces within the earth's mantle and reemplaced tectonically, or by solid or quasi-solid flow into crustal rocks. The ultramafic complexes, of which podiform chrome districts are a part, are called alpine-type complexes because they are always characterized by intense regional deformation (Jackson and Thayer, 1972). It is postulated that the settled chromite layers (chromitite) were relatively well consolidated and cohesive as compared to the surrounding semisolid mixture of crystals and liquid, or mush, which was able to physically entrain and support the higher specific gravity chromite masses by virtue of motion and high effective viscosity. Broken segments of the chromite layers were jumbled and carried along in the moving stream and were frozen in place in varying attitudes and locations as the crystal mush finally solidified. In periods of relative quiescence, the chromite agglomerates would sink even in the mush in a manner simulating Stokes law according to which the velocity of descent is proportional to the square of the diameter of the body. This could explain the extreme paucity of very large podiform bodies (1 to 15 million tons) and the comparative abundance of small bodies.

The Selukwe district of Zimbabwe described by Cotterill (1969) possesses characteristics of both podiform and stratiform deposits. The district appears to consist of sliced-up remnants of an originally stratiform complex. Within some slices, ore zones (though not bodies) can be followed for the length of the slice. The actual ore bodies are most generally described as lenses or "pipelike" and are discontinuous or irregularly distributed. Zones of occurrence of ore bodies tend to extend the full strike distance of a slice but in the dip direction ore distribution is mostly restricted to much less than half the extent of the ore zone. Much of the chromite is strongly sheared, i.e., microbrecciated or mylonitized. Cotterill (1969) believes that the chromite lenses represent original cumulus chromite that settled in local furrows or depressions caused by buckling of silicate layers during tectonic movements. He does not believe the lenses were reemplaced through a semisolid silicate matrix but owe their present distribution to the segmentation of an original ultrabasic complex into slices. Jackson and Thayer (1972) classify the Selukwe district as a stratiform complex which it may be, viewed broadly petrogenetically. But from the practical viewpoint of finding ore bodies and calculating reserves, the Selukwe district is more closely akin to podiform districts than it is to classic stratiform deposits such as the Bushveld or Great Dyke. As more knowledge is gained, the transitional events between original chromite accumulation and final emplacement will become better known. In the Selukwe district these events seem somewhat more clear than, say, in Turkey or Masinloc but still far from obvious.

The implications of the petrogenetic hypotheses on exploration and prospecting for podiform ore bodies could be profound. If the podiform bodies are broken up remnants of originally stratiform deposits, only a tiny fraction of the original ore bodies have ever been found. How can the number and size of the original layers be estimated from the remnants? How much remains at economically exploitable levels, and do the fragments have a decipherable pattern of distribution? These are unanswered questions and the estimation of ultimate reserves of any podiform district is largely speculation. The fact that some of these districts have, in the past, managed to maintain stated reserves at, say, 10 times

annual production for 10 or 20 years indicates the estimators had no real idea of the reserves, but gave developed ore plus a reasonable inference based on experience, intuition, and an optimistic outlook.

Although there is no present scientific methodology for extrapolating podiform reserves, there are guides to prospecting that increase the probability of finding new ore bodies.

A great deal of interest has been shown recently in methods of exploration and prospecting for chrome ores. As mentioned previously, stratigraphic methods are best applied to stratiform deposits. But geophysical methods have had limited success as aids to exploring these deposits as at Kemi, Finland, where the extension of ore was traced under glacial deposits. The main interest lies in ore-finding methods for podiform deposits. The relationships of structural and textural features of ore bodies to those of the host rocks in some districts give clues to the probable locations of other ore bodies. These are empirical relationships and do not assure the occurrence of new ore bodies. Of geophysical methods, magnetic methods have been of little use. Gravimetric methods have had limited success in a few cases (Yüngül, 1956; Davis, et al., 1957). Hosking (1964) describes the possibilities of using geochemical methods for chrome ore prospecting mainly to narrow the areas for drilling. Drilling, drifting, or trenching near known ore bodies is the usual current method of discovering new bodies.

5. Clays*

INTRODUCTION

The term *clay* is somewhat ambiguous unless specifically defined, because it is used in three ways: (1) as a diverse group of fine-grained minerals, (2) as a rock term, and (3) as a particle-size term. Actually, most persons using the term *clay* realize that it has several meanings, and in most instances they define it. As a rock term, *clay* is difficult to define because of the wide variety of materials that compose it; therefore, the definition must be general. *Clay* is a natural earthy, fine-grained material composed largely of a group of crystalline minerals known as the clay minerals. These minerals are hydrous silicates composed mainly of silica, alumina, and water. Several of these minerals also contain appreciable quantities of iron, alkalies, and alkaline earths. Many definitions state that a clay is plastic when wet. Most clay materials do have this property, but some clays are not plastic; for example, halloysite and flint clay.

As a particle-size term, *clay* is used for the category that includes the smallest particles. The maximum-size particles in the clay-size grade are defined differently on various grade scales. Soil investigators and mineralogists generally use 2 micrometers as the maximum size, whereas the widely used scale by Wentworth (1922) defines *clay* as material finer than approximately 4 micrometers.

Some authorities find it convenient to use the term *clay* for any fine-grained, natural, earthy, argillaceous material (Grim, 1968). When used this way, the term includes *clay*, *shale*, or *argillite*, and some argillaceous soils.

Even though no standard definition of the term *clay* is accepted by geologists, agronomists, engineers, and others, the term is generally understood by those who use it. *Clay* is an abundant natural raw material, and it has an amazing variety of uses and properties which will be discussed.

As industrial minerals, clays are a complex group that consists of several mineral commodities, each having somewhat different mineralogy, geologic occurrence, technology, and uses. In this section, these commodities are organized as follows: (1) bentonite and fuller's earth; (2) kaolin, ball clay, halloysite, and refractory clays; and (3) miscellaneous clay and shale. Bentonite and fuller's earth are grouped together because they are closely interrelated. Though bentonite is a term based on mineral composition and fuller's earth is a term based on use, the two are virtually inseparable, because much, but by no means all, clay sold as fuller's earth is actually bentonite. The overlapping of the two terms is particularly evident where both bentonite and nonbentonite fuller's earth are used for the same purposes or products, such as in drilling muds, bleaching or clarifying fats and oils, and carriers for insecticides and fertilizers. Kaolin, ball clay, halloysite, and refractory clays are grouped together because they consist mainly of minerals of the kaolin group. Miscellaneous clay and shale is a grouping of several fine-grained materials of the type referred to as common clay in some reports.

BENTONITE AND FULLER'S EARTH

Definitions and Classifications

The term *bentonite* was first proposed in 1898 by Knight (1898), a year after he had named this clay *taylorite*; *taylorite*

was found to be preoccupied. The name *taylorite* was after the Taylor ranch, the site of the first mine, near Rock River, WY, and the name *bentonite* is from the Benton Shale in which the clay was thought at that time to occur. The Benton Shale was, in turn, named after Fort Benton, MT, located more than 644 km (400 miles) north of Rock River.

Early in the 20th century, several geologists recognized that bentonite, mainly in beds in Cretaceous and Tertiary rocks, originated from transported volcanic materials. This recognition led to definitions based on origin, the one most widely quoted and generally accepted by geologists is the following definition by Ross and Shannon (1926):

Bentonite is a *rock* composed essentially of a crystalline clay-like mineral formed by devitrification and the accompanying chemical alteration of a glassy igneous material, usually a tuff or volcanic ash; and it often contains variable proportions of accessory crystal grains that were originally phenocrysts in the volcanic glass. These are feldspar (commonly orthoclase and oligoclase), biotite, quartz, pyroxenes, zircon and various other minerals typical of volcanic rocks. The characteristic clay-like mineral has a micaceous habit and facile cleavage, high birefringence and a texture inherited from volcanic tuff or ash, and it is usually the mineral montmorillonite, but less often beidelite.

The difficulty in applying the foregoing definition to bentonite as an industrial mineral commodity is that it is based on origin and is restrictive to an ash, tuff, or volcanic glass parent material. Therefore, bedded deposits consisting of the clay minerals required by this definition but having uncertain origin or parent materials cannot properly be called bentonite. Furthermore, many deposits in the western United States and in other countries that have formed from rocks other than the types required by the definition are being mined and sold as bentonite.

Perhaps the best definition of bentonite as an industrial mineral is one given by R. E. Grim in a plenary lecture at the International Clay Conference (AIPEA) at Madrid, Spain, June 27, 1972. According to this redefinition, which will be used in this section, bentonite is a clay consisting essentially of smectite minerals (montmorillonite group of some usages), regardless of origin or occurrence. This definition solves the problem of the difference between the geologic and industrial usages of the term and overcomes the difficulty in assigning a name to smectite clay that formed from igneous rock other than ash, tuff, or glass, or those of sedimentary or uncertain origin. However, bentonite, when used with this meaning is still a rock term (consisting of more than one mineral), and it will not be possible to distinguish it from fuller's earth in many instances.

One way of classifying bentonite is based on its swelling capacities when wet or added to water. Bentonite having sodium (Na^+) as either the dominant or as an abundant exchangeable ion typically has very high swelling capacities and forms gel-like masses when added to water. Bentonite in which exchangeable calcium (Ca^{++}) is more abundant than other ions has much lower swelling capacities than sodium varieties. Some calcium types swell little more than common clay, and most crumble into granular masses in water. Intermediate calcium-sodium bentonites, the so-called mixed types, tend to swell moderately and to form gel of lesser volumes than equal masses of the sodium type. Bentonite, because of the general relationship of swelling and exchangeable ion characteristics, is commonly divided into the high-swelling or sodium, low-swelling or calcium, and moderate-swelling or intermediate types. The term *subben-*

*Excerpt from Patterson, S.H., and Murray, H.H. (revised by Murray, H.H.), 1983, "Clays," *Industrial Minerals and Rocks*, 5th ed., Vol. 1, S.J. Lefond, ed., AIME New York, pp. 585-651.

tonite (Davis, et al., 1940) is used inconsistently in industry for the low or moderate-swelling varieties. The authors believe the use of this term should be discouraged because of its implication of a low quality or low value and the lack of a mineralogical or use basis for it.

In the United States, bentonite is also classified by geographic location and the uses for which it is sold. Inasmuch as most of the low-swelling calcium type occurs in states bordering the Gulf of Mexico, this variety is commonly called *Southern bentonite*. The largest high-swelling sodium bentonite deposits and the major producing districts are in Wyoming and adjacent states. Therefore, this bentonite is commonly called *Wyoming* or *Western* type. Such terms as drilling mud bentonite, foundry bond bentonite, and taconite bond bentonite relating directly to use are applied in marketing. Other terms including high and low-yield bentonite, high and low-gel bentonite, and high and low-strength bentonite are also used to distinguish different grades.

The varied classifications notwithstanding, bentonite occurs in so many different varieties that some cannot logically be classified according to any of the foregoing groupings. One of these types is hectorite, which is a high-swelling lithium-bearing variety of smectite occurring mainly in California and adjacent states. It is, therefore, not a Wyoming type, and it occurs even farther west than the so-called western bentonites. Others are bentonites having magnesium (Mg^{++}) or hydrogen (H^+) as the most abundant or dominant exchangeable ion. These types are neither sodium nor calcium varieties, and apparently some are low swelling, whereas others have rather high-swelling capacities.

Still another type of bentonite, the so-called potassium type, K-bentonite, or metabentonite, occurs in Ordovician and other Paleozoic rocks at many places in Appalachian and Mississippi Valley regions and elsewhere. This bentonite, which is generally thought to have formed from volcanic ash, consists mainly of illite and mixed-layer minerals. Smectite minerals are ordinarily present in only minor quantities. Because of its mineral composition, this bentonite contains appreciably more potassium than most other types. The meta prefix originates from the idea that this bentonite was altered by low-grade metamorphism or diagenesis. Apparently, the only attempt to use K-bentonite in the United States was when five or six carloads were mined near Dayton, Rhea County, TN, about 1928; this bentonite was used for purifying lard (Gildersleeve, 1946), and no further mention of this type will be made.

The term *fuller's earth* is more or less a catchall for clay or other fine-grained earthy material suitable for bleaching and absorbent and certain other uses. It has no compositional or mineralogical meaning. The origin of the term dates back into antiquity; it was first applied to material used in cleansing and fulling wool, thereby removing the lanolin and dirt from it. When in the latter half of the last century it was found that some earths used for fulling would also serve in decolorizing and purifying mineral, vegetable, and animal oils, and the term *fuller's earth* was modified to include this usage.

Extensive use of fuller's earth in processing mineral oils in the first half of this century and the virtual end of its use in fulling fiber led to the general application of the term, fuller's earth, as meaning primarily earth used in petroleum processing. Further modification of the meaning came about as other uses developed for the earth and replaced oil processing as the major use. The term fuller's earth is retained, however, for fine-grained materials used for many purposes. Most of these uses require absorbent properties in one form or another, but the properties required for some uses, such

as certain drilling muds and fillers, are other than absorbency and, therefore, result in further modification of the term.

The classification and understanding of fuller's earth are also complicated by several terms having more or less duplicate or overlapping meanings. When applied in the oil-processing sense, fuller's earth has the same meaning as *naturally active clay*. Fuller's earth and other clays which are treated with acid or otherwise altered to improve their desirable properties are called *activated clay* (Torok and Thompson, 1972). The terms *bleaching clay* and *bleaching earth* are applied mainly to both naturally active and activated clay, but they also include activated bauxite (Rich, 1960). Both naturally active and activated clays are included under the term *absorbent clays* (Nutting, 1943); therefore, this term has nearly the same meaning as bleaching clay. The term *absorbent clay* is applied to fuller's earth used for a wide variety of absorbing purposes which are different from that of processing oils.

History and Use

Bentonite: Bentonite mining began on the Taylor ranch near Rock River, WY, in 1888. This bentonite reportedly was shipped crude to Philadelphia where it sold for \$25 a ton and was used in making cosmetics. A mine was opened in the Upton, WY, district on the western side of the Black Hills in 1903. The early method of drying was to rake the bentonite by hand over steel plates heated by wood or coal fires.

The date of the first mining of southern bentonite is somewhat conjectural because of the confusion between the terms bentonite and fuller's earth. One fuller's earth deposit near Gonzales, TX, that is almost certainly bentonite was mined as early as 1906, and another deposit in that same state mined during the Civil War (Lang, et al., 1940) may also have been bentonite. Large-scale mining of calcium-type bentonite began in Mississippi in the early 1930s (Bicker, 1970), and bentonite deposits were used as fuller's earth in several states about this time.

The value of bentonite as foundry-sand bond was recognized in the 1920s, and the iron and steel foundries have since been major consumers of bentonite. Bentonite was first used as drilling mud in the late 1920s or early 1930s, and bentonite is still one of the most efficient materials for drilling muds where the rocks penetrated contain only fresh water. The high-swelling Wyoming bentonite is the most efficient type for drilling mud, but the high-viscosity properties of hectorite make it useful in muds (Larsen, 1955). Some Texas bentonite is also used for drilling muds, particularly in shallow wells, and commonly it is treated with soda ash, polymers, or other chemicals to make it suitable for this use. Low-quality bentonite when sold for use in drilling mud is commonly classified merely as clay rather than bentonite (Anon., 1972d).

Bentonite production remained small during the first few decades of mining, and the first yearly total sufficiently large to be separated from miscellaneous clays in the US Bureau of Mines statistics was in 1930 when production was only a few thousand tons. Demands for bentonite increased during World War II, but a yearly total of 907 kt (1 million tons) was not reached until 1950. More than 1.8 Mt (2 million tons) was produced in 1966. Bleaching clay (oil refining, filtering, clarifying, and decolorizing), drilling mud, iron-ore pelletizing, and foundry-sand bonding have been the major uses of bentonite since World War II. Beginning about 1950, steel companies used Wyoming-type bentonite as a bond for pelletized taconite ore.

In addition to the major uses, bentonite is used in many miscellaneous products, and hundreds of patents for speciality uses have been issued or applied for. The speciality uses include filtering agents (one of which is a high-value product for clarifying wine, and another is a less costly one for treating waste water), water impedance (preventing seepage loss from reservoirs, irrigation ditches, and waste-disposal ponds, and seepage through basement walls, tunnel walls, and other structures), ingredients in cosmetics, animal feed, pharmaceuticals, colloidal fillers for certain types of paints, an additive to ceramic raw materials to increase plasticity, fire-retarding materials, and for many other purposes (Papin, 1964). The white bentonites occurring in Texas and Nevada and imported from Italy are particularly suitable for many of the speciality products, and a great deal of research evaluating them for many uses has been done. One of the unique uses of high-swelling bentonite that is likely to increase is in the "slurry trench" or "diaphragm wall" method of excavation in construction in areas of unconsolidated rock or soil (Blackman, 1969; Lang, 1971). Considerable quantities of bentonite were once used in making catalysts for petroleum refining, but the market for these types of catalysts in the United States declined after World War II. However, sizable quantities of catalysts have been produced from bentonite and similar clays in Japan, the United Kingdom, and elsewhere in recent years. Acid-activated bentonite is used for bleaching oils and in making multiple-copy paper requiring no carbon paper.

Fuller's Earth: Published reports give rather confusing accounts of the discovery of fuller's earth in the United States. Several state that fuller's earth was discovered in this country in 1893 near Quincy, FL, by the Owl Commercial Co. (predecessor of the present makers of White Owl cigars) during an attempt to burn brick from clays on tobacco property. The clay was not suitable for making brick, but an Alsatian immigrant employed as a farm worker recognized that it was similar to fuller's earth mined in Germany. His observation led to development of the first mine near Quincy two years later and to the use of this clay in processing mineral oils. Fuller's earth had been mined on a small scale, however, in Arkansas in 1891 (Miser, 1913), and tested for use in the refining of cottonseed oil.

Both of these reported discoveries are related to the use of fuller's earth in processing oils and fail to note its earlier use for other purposes. Clays and other earthy materials were undoubtedly used by the early settlers from Europe in cleansing wool and other materials. Little effort was made to search the historical records and to document this, but it was found that soldiers stationed near Perth Amboy, NJ, used Woodbridge fire clay for cleansing buckskins during the Revolutionary War (Cook and Smock, 1878). Fuller's earth associated with an iron-ore bed near Kent, CT, had been mined in the early 1800s (Silliman, 1820), and fuller's earth near Falls City, TX, had been used to bleach sugar during the Civil War (Lang, et al., 1940). Also, American Indians were reported to have used bentonite in cleaning blankets, and they probably dug it for other cleansing purposes before the Columbian period.

The use of fuller's earth in the refining of oils continued to be the major one for many years. The demand for fuller's earth for processing mineral oil increased rapidly in the first part of this century and reached a peak of approximately 288 kt (317,000 tons) in 1930; this was 91.1% of the total United States production that year. The production of fuller's earth for this purpose began to decrease thereafter, especially when activated bauxite was introduced in 1937 and mag-

nesium silicate in 1940 as more efficient substitutes. The market for this use was also depressed by improvements in refining methods, which produce oils requiring little purification or bleaching. In recent years, the production of fuller's earth for use in refining mineral oils has maintained a rather uniform rate of 32 to 36 kt/a (35,000 to 40,000 tpy). The use of fuller's earth in processing animal and vegetable oils has never been a major one and has decreased to the point where it is included as a part of the miscellaneous uses in the US Bureau of Mines *Minerals Yearbooks*.

Palygorskite (attapulgit) fuller's earth was first sold for drilling mud in 1941. The market for this use expanded slowly and has maintained a level of 7 to 10% of the total United States production during the last few years. Most of the fuller's earth sold for drilling mud comes from the southern part of the Meigs-Attapulgis-Quincy district of Georgia and Florida. Palygorskite clays produced in this area are superior to most other fuller's earth for muds used in drilling salt formations, but because of high water loss, they are inferior to bentonite where the rocks drilled contain no saltwater.

Fuller's earth was used in significant quantities as a carrier for insecticides and fungicides by 1950, and the market for this use has grown at a rather uniform rate since that year.

The use of fuller's earth granules for absorbent purposes began during the 1930s, but this use did not expand significantly until the World War II period when fuller's earth was used as an absorbent for greases, oil, water, chemicals, and other undesirable substances on the floors of factories, filling stations, canning plants, aircraft hangers, decks and engine rooms of ships, and other installations. The absorbent granules are porous and ordinarily weigh less than 481 kg/m³ (30 pcf). Because of their light weight, size, porosity, and absorbent properties, the granules are suitable for many uses, and since World War II many different markets for them have developed. Among other uses, they are now sold for litter and bedding for poultry, pets, and other animals, and as a soil conditioner in greenhouses and for golf courses,

Geology

Mineralogy: The principal clay mineral in bentonite is smectite, and many fuller's earth deposits also consist chiefly of this mineral. The term *smectite* is applied as a group name, and *montmorillonite* is a mineral species name. This usage conforms to the growing acceptance of the term smectite and does away with the confusing use of montmorillonite as both mineral species and group names. Montmorillonite, including both sodium and calcium varieties, is the most common member of the smectite group occurring in bentonite. However, saponite, a magnesian smectite, and hectorite, a lithium-bearing magnesian variety, are the major minerals in some bentonites.

Smectite minerals occur in extremely small particles; therefore, detailed information on them is difficult to obtain and is, in part, based on theoretical considerations. As the mineralogy of this group of clays is complex, the reader is referred to authoritative books and other references; only the following brief summary will be given here.

According to the most generally accepted structure, smectite consists of two silica tetrahedral sheets with a central octahedral sheet. The theoretical structural formula is $(\text{OH})_2\text{Si}_2\text{Al}_2\text{O}_{10} \cdot n\text{H}_2\text{O}$, and the theoretical composition without interlayer material is SiO_2 , 66.7%; Al_2O_3 , 28.3%; and H_2O , 5%. However, smectite always differs from the foregoing theoretical formula and composition because of sub-

stitutions of various ions for silicon in the tetrahedral coordination and for aluminum in the octahedral sheet. Furthermore, the substituted ions are thought to be commonly of different valence than the theoretical ion replaced, which results in an unbalancing of the charge in a unit of smectite. This charge deficiency is balanced by exchangeable ions, which vary considerably and result in further differences in the compositions of smectite. Cations which are exchangeable in bentonite include sodium, calcium, potassium, magnesium, lithium, and hydrogen. The exchange capacity of most bentonite is within the range of 60 to 150 milliequivalents per 100 g.

Unit layers of smectite are thought to be stacked with the oxygen layer of one silica tetrahedral sheet adjacent to the similar layer in the neighboring unit. Only a very weak bond exists between neighboring units, and water or other polar molecules can enter between unit layers causing the lattice to expand in the *c* direction. This expansion by polar molecules and the collapse of expanded units with heat, which can be recognized by X-ray diffraction methods, is applied in studying smectite and distinguishing members of this group from other clay minerals.

The ion-exchange characteristics have an important role in controlling or influencing the physical properties of bentonite and the bentonite fuller's earths. In general, those bentonites that have Na^+ as the dominant exchangeable ion have very high swelling capacities and colloidal properties, and those in which Ca^{++} is the dominant ion tend to swell little more than other clays. Because of their high colloidal properties, high-swelling sodium bentonites are valuable as drilling muds and other uses requiring thixotropic suspensions. The calcium varieties usually have little value for such uses without beneficiation by the addition of soda ash or other chemicals, and even when so treated, are not ordinarily as efficient as the sodium types. The type of exchangeable ion also has a major role in controlling the bonding characteristics. As pointed out by Grim (1962), sodium bentonites have very strong foundry sand bonding properties after drying (dry strength), but only moderate strengths when moist or wet (green strength). Calcium bentonites, on the other hand, have high green strengths and low to moderate dry strengths. However, part of these differences in bond strengths may be due to particle size or other characteristics, and there is some evidence that the dry strength of some calcium bentonites can be increased by lengthening the mulling (mixing) time in the preparation of foundry sand.

All bentonites contain mineral impurities, which vary considerably in type and quantity present. A few are contaminated with minor quantities of clay minerals other than smectite, such as kaolinite and illite. The common nonclay minerals in bentonite include those listed in the older definition by Ross and Shannon (1926), and minor quantities of most of the accessory minerals in volcanic rock also may be present. Selenite is abundant in many deposits, and some beds contain carbonate veins and concretions. Zeolite minerals and opal, cristobalite, or other forms of poorly ordered silica are present in some bentonite deposits in western United States and at several other places in the world. Some deposits are contaminated with incompletely altered parts of the rock from which they formed. The vitric latitic tuff remaining in the bentonite at Cheto, AZ (Sloane and Guilbert, 1967), is an example of this type of material.

The principal fuller's earth deposits other than the bentonite type consist of palygorskite (attapulgite) and sepiolite. According to Bradley (1940), palygorskite has an ideal formula of $(\text{OH}_2)_4(\text{OH})_2\text{Mg}_5\text{Si}_{18}\text{O}_{20} \cdot 4\text{H}_2\text{O}$, but substitution of

Al^{3+} for either Mg^{++} or Si^{4+} takes place. It consists of two silica chains linked in amphibolelike structures and has both monoclinic and orthorhombic symmetry (Christ, et al, 1969). Sepiolite, $(\text{Si}_{12})(\text{Mg}_9)\text{O}_{30}(\text{OH})_6(\text{OH}_2)_4 \cdot 6\text{H}_2\text{O}$, is thought to have three pyroxene-type chains (Grim, 1968), and therefore, the unit cell is somewhat larger than for palygorskite. Both palygorskite and sepiolite typically occur in fibrous and elongate lathlike particles. Sepiolite is also the mineral forming meerschaum.

Other nonbentonite fuller's earths include an uncommon type of rock called opal claystone (Heron, et al., 1965). This rock is more than three-fourths opal or another form of poorly ordered silica, and the remainder is montmorillonite and other mineral impurities. It was mined in South Carolina in the early part of this century and used for bleaching oil. Nonbentonite clays that have been used as fuller's earths in the past include the Anna kaolin in Illinois, halloysite in Utah (Schroter and Campbell, 1940), and glacial clays in Massachusetts. In addition to these nonbentonite clays, there are extensive deposits of fuller's earth consisting of very impure montmorillonite that are not ordinarily thought of as being bentonite. Two such deposits are the Porters Creek Clay (Paleocene) in the Mississippi Embayment region and the Twiggs Clay Member of the Barnwell Formation (Eocene) in Georgia.

Occurrence: Though bentonite deposits of Jurassic age are extensive in western United States and elsewhere in the world, virtually all deposits mined to date are of Cretaceous age or younger. All but a very minor tonnage of the high-swelling Wyoming-type bentonite produced has been mined from beds of Cretaceous age, and more than three-fourths of the total has come from a single formation—the Mowry Shale. The southern or calcium bentonite is mainly in formations of Cretaceous, Eocene, and Miocene age. The abundant miscellaneous bentonite deposits, other than the high-swelling type, in the western states are mainly of Tertiary age. Deposits scattered through Nevada, California, Oregon, and Idaho are mainly in upper Tertiary rocks, and many are thought to be Late Miocene or Pliocene in age. The widely known Cheto bentonite near Chambers, AZ, is in the Bidahochi Formation of Pliocene age, and deposits mined in western Oklahoma are also in Pliocene rocks. Deposits in the Ash Meadows district, NV, occur in rocks mapped by Denny and Drewes (1965) as Pleistocene in age, and if this age assignment is correct, they are among the youngest bentonites in the world.

Most bentonite occurs in beds or lenticular bodies aligned along a definite stratigraphic zone. Some beds extend for more than 322 km (200 miles), and other deposits, particularly the lenticular ones, are only a few hundred yards in diameter. Deposits mined range from about 0.3 to more than 9 m (1 to 30 ft) in thickness. Bedded deposits ordinarily have a characteristic sharp contact with underlying rocks and a gradational one with overlying strata. Deposits formed by hydrothermal processes tend to be irregularly shaped and to grade into the host rock in all directions.

Most bentonite, including both the high and low-swelling types, has a characteristic waxy or soaplike texture. Parts of deposits near the surface tend to be light-yellowish green or gray when the natural moisture is present and to become lighter in color when they dry. Deposits under considerable overburden tend to be bluish gray. The change to lighter shades near the surface is related to the oxidation of iron. Typical outcrops of high-swelling bentonite have a popcorn-like or frothy texture caused by alternate swelling and drying of the bentonite. Outcrops of low-swelling types commonly

have a cracked appearance thought by some to resemble alligator hide.

Most bentonite in North America and elsewhere occurs in sedimentary rocks and was formed in place from volcanic ash or tuff. Some deposits have been formed by hydrothermal alteration of volcanic or other igneous rock, and other deposits of nearly pure smectite may be accumulations that were transported and deposited in marine or alkaline lake water with only minor postdepositional alteration.

The extensive palygorskite (attapulgitic) fuller's earth deposits in the southern part of the Meigs-Attapulgius-Quincy district, Georgia and Florida, occur as tabular lenses and discontinuous beds in the Hawthorn Formation of Miocene age. This clay is green and bluish gray, and most of it has a waxy or soaplike texture.

In addition to the deposits in the United States, palygorskite fuller's earth is also mined in the following regions: (1) Pout district near Mbour, Senegal (Wirth, 1968); (2) Ukrainian district, USSR (Ovcharenko, et al., 1967); and (3) Mudh district, India (Siddiqui, 1968). The Senegal deposits are in marine beds of Early Eocene age. The Ukrainian palygorskite is interbedded with bentonite. Deposits in India occur between fossiliferous limestones and apparently are marine in origin.

Insofar as the authors are aware, the only sepiolite fuller's earth mined at the time this report was written is in the Vallecas and another district in Spain (Anon., 1972b). However, economic sepiolite deposits have been discovered recently in the Ash Meadows district, Nevada (private communication). The Spanish deposits occur in an evaporite sequence of Tertiary age. The Nevada deposits are closely associated with calcium, sodium, and magnesium bentonites of Pleistocene age.

Origin: The evidence for most bedded bentonite having formed from volcanic materials transported considerable distances in the atmosphere was presented by several geologists early in the century, including Hewett (1917), Wherry (1917), and recently by Slaughter and Earley (1965). This conclusion is based primarily on the purity of smectite, on the fact that the nonclay minerals in bentonite are angular and of the type occurring in volcanic rock, rather than mixtures of rounded grains characteristic of detrital sediments, and on the presence of relict shard textures in many bentonites (Ross and Shannon, 1926). Ample evidence supports the conclusion that the parent ash of most bentonite was deposited under marine conditions, but a few deposits apparently accumulated in alkaline lakes (Papke, 1969). As would be expected, different bentonites have formed from volcanic rock of somewhat different types, and the most common parent materials range from andesite to rhyolite in composition. Opinions differ concerning the process and time of alteration of the ash. Several authors have noted that change in ash would have begun with its contact with water, but when the alteration was completed is questionable. Papke (1969) believes that one type of bentonite deposit formed in alkaline lakes soon after deposition and another type formed more slowly as the result of alteration by ground water. Alteration by ground water requires burial by younger rocks and probably regional uplift and a considerable interval of geologic time. In the author's opinion, changes have taken place in bentonite deposits throughout virtually their entire geologic history. Some deposits may have been altered extensively before burial beneath younger rocks. However, the prominent cherty zone below several beds points to the downward transport of silica by ground water from altering deposits; this must have taken place after burial.

Bentonite formed by hydrothermal activity occurs in Nevada (Papke, 1969), California (Kelley, 1966), Spain (Anon., 1972b), and elsewhere. Deposits of this type commonly are associated with other minerals known to have formed by hydrothermal processes. They also tend to occur in irregularly shaped bodies rather than in beds, and they ordinarily grade into the host rock through partially altered zones. The distribution and shape of bentonite formed hydrothermally are commonly controlled by fault zones, joints, and other geologic features providing access for heated water.

Alteration of volcanic ash or tuff in restricted alkaline lakes heated by hot-spring activity is also thought to have formed bentonite (Ames, et al., 1958). The hectorite deposits in California probably formed this way, and this clay passed through an intermediate stage in which most of the ash was altered to zeolite. A magnesium bentonite called amargosite formerly mined near Shoshone, CA, also formed by the alteration of vitric volcanic material by hot springs (Sheppard and Gude, 1968).

Though the authors have doubts about the theory, some bentonite deposits are thought to have been deposited mainly in the form of smectite minerals. According to this explanation of origin, smectite minerals, having formed by weathering of volcanic or other igneous rocks, were transported, separated from impurities, and deposited. This theory has been applied to explain the origin of deposits in India (Siddique and Bahl, 1965), the USSR (Tazhibayeva and Galiyev, 1972), and Nevada (Papke, 1969). Bentonite fuller's earth deposits in the United Kingdom were thought by Robertson (1961) to have been transported from smectite-rich soils on the European landmass. Such soil would have formed mainly on nonigneous rocks.

As most fuller's earth deposits are bentonites, they have the same origins; however, some fuller's earths consist of minerals other than smectite and may be of quite different origin. The palygorskite (attapulgitic) fuller's earth deposits in Georgia and Florida are one type that probably formed in a different way. These deposits have been investigated by several geologists and mineralogists, and no one has found convincing evidence of any volcanic materials having ever been present. The first author has investigated these deposits in detail and believes that the palygorskite in them formed in place from seawater evaporating in a tidal-flat environment. This theory is essentially the same as the "neof ormation" idea of Millot (1964).

Distribution of Deposits

North America: United States—SOUTHERN BENTONITE AND FULLER'S EARTH. Southern or calcium bentonite is now mined in Texas, Mississippi, Alabama, Oklahoma, and Louisiana (Teague, 1972). Undeveloped bentonite deposits occur in South Carolina (Robinson, et al., 1961).

Fuller's earth is produced mainly in the southern states; and the Meigs-Attapulgius-Quincy district, Georgia and Florida is the leading fuller's earth-producing district in the United States.

Fuller's earth used mainly in bleaching animal and vegetable oils is now produced in Texas, and historically this state has ranked with the leading producers. The fuller's earth produced in Texas is mined from bentonite beds.

WYOMING OR HIGH-SWELLING BENTONITE DEPOSITS. The North Rocky Mountains-High Plains region has led the world in the production of Wyoming or high-swelling bentonite since the first mining of this clay. The major producing districts are as follows: (1) the northern and western Black Hills districts, Wyoming, Montana, and South Dakota; (2)

Kaycee-Midwest, Wyoming; (3) Greybull-Lovell, Wyoming and Montana; (4) Vananda, Montana; and (5) Chinook-Malta-Glasgow, Montana.

HECTORITE. Virtually all the hectorite mined recently has been near Hector, CA, the type locality. The hectorite occurs as a waxy soft nodular layer ranging from 1.8 to 2.4 m (6 to 8 ft) in thickness. It is associated with sandstone and clay beds of Tertiary age that accumulated in an alkaline lake environment. The beds below the hectorite contain travertine formed as the result of hot-spring activity (Ames, et al., 1958). The valuable hectorite deposits are overlain by Quaternary basalt.

A large deposit of hectorite has been discovered recently in the Amargosa Valley, California (private communication). Plans for mining and processing this clay were in an advanced stage of preparation when this report was written.

In addition to the Hector and the Amargosa districts, hectorite also occurs 26 km (16 miles) north of Amboy, CA, and in Yavapai County, AZ (Norton, 1965). Deposits not known to the authors probably occur at other localities, and there are many areas where the geologic conditions are favorable for more discoveries.

OTHER DEPOSITS IN WESTERN STATES. Bentonite (other than the Wyoming type and hectorite) and fuller's earth deposits are scattered throughout the western states. In general, bentonite production from these deposits has been small, as compared with that from the Wyoming and Southern types, because many of these clays are of lower quality and all of them are more distant from the major consumers. One district in which bentonite has been mined continuously for a long time is in the vicinity of Chambers [Cheto], AZ (Kiersch and Keller, 1955). This bentonite is a low-swelling clay used as bleaching earth and in making desiccants. Bentonite used for preparing livestock feed is mined in southwestern Idaho, southern California, and probably elsewhere. Deposits in central Oregon are used in the preparation of retardants used in fighting forest fires. Some of the white bentonite mined in Nevada is used in pharmaceuticals and beauty aids. A bentonite in the Ash Meadows district composed of saponite (Papke, 1969) was mined extensively several decades ago, and other deposits in the state have been mined for use in water impedance and for other purposes. Low-swelling or calcium-type bentonite also occurs and is produced in the region containing the Wyoming or high-swelling bentonite. Low-swelling bentonites are mined from deposits in the northern Black Hills and the flanks of the Big Horn Mountains. This bentonite is marketed primarily for foundry-sand bonding.

The most active fuller's earth-producing districts in the western states are in Kern County, CA. In addition to the deposits in Kern County, bentonite near Olancho and probably deposits at other localities in California have been processed for filtering and decolorizing agents in recent years.

RESOURCES. Resources of bentonite and fuller's earth in the United States are very large. The reserves of bentonite are at least one billion tons, and the total resources, including all bentonite that will be eventually suitable for one use or another, are considerably larger. This reserve estimate of one billion tons includes very large deposits that have a quality suitable for binding iron-ore pellets but that would be classed as submarginal for drilling mud and several speciality uses. The reserves of very high quality drilling-mud bentonite are limited and are much in demand. Resources of fuller's earth are tentatively estimated at two billion tons. However, almost any figure could be used here, if all the clays equal in quality to the lowest grade material used as bleaching clay in the

past were included. A large part of the fuller's earth resources is in the extensive Porters Creek Clay and the Twiggs Clay Member of the Barnwell Formation. These deposits are suitable for use in absorbent granules and certain other fuller's earth products, but they are not used in drilling mud and several of the speciality products.

Canada—Bentonite occurs in beds of Cretaceous and Tertiary ages at many places in western Canada (Ross, 1964; Spence, 1924). The major producing districts are Onoway (Baroid Canada, Ltd.) and Rosalind (Dresser Industries, Inc.) in Alberta and in the Pembina district (Pembina Mountain Clays, Ltd.) in Manitoba. Bentonite has also been mined near Princeton, BC, and deposits near Avonlea, Sask. (Anon., 1971), and along the Mackenzie River in the vicinity of Inuvik, NWT, have been investigated by industry.

According to Ross (1964), only a very few million tons of bentonite reserves have been proved in Canada. However, the potential resources of bentonite in the country must be very large, considering the large areas now known to contain scattered deposits and the general similarities of strata to Cretaceous and Tertiary rocks in the United States known to contain bentonite.

Mexico—The German firm Süd-Chemie AG with its Mexican affiliate Tonsil Mexicana SA has operated a bentonite plant in Puebla since 1967 (Anon., 1969k), and another plant is active intermittently at Monterrey. Bentonite and fuller's earth also occur in Querétaro, Michoacán, and Guanajuato, and a few of these deposits have been mined on a small scale (Esquivel and Zamora, 1958). Apparently, most Mexican bentonite deposits occur in sedimentary rocks, and some of these are of the nonmarine type.

South America: Argentina—Bentonite deposits are scattered throughout several provinces in Argentina (Bordas, 1947). The principal deposits mined are as follows:

Principal Deposits	Province
Rio Chico	Chubut
El Alamo y Las Hegueras	Mendoza
El Catalán	Neuquén
Del Lago Camino y Rob	Río Negro
La Emilia y Cristina	San Juan

A few thousand tons of fuller's earth are also produced each year. The fuller's earth deposits mined are in La Rioja and Río Negro provinces.

Brazil—A plant processing montmorillonite clays for use as foundry-sand bond was built at Sacramento, Minas Gerais, in 1962 (Anon., 1962). Bentonite has also been found at several other localities in the country.

Peru—Bentonite and fuller's earth occur in the provinces of Pisco, Canete, Paita, and Contralmirante Villar, and elsewhere (Caberra, 1963). Bentonite has been mined and used in iron-ore pelletizing in Peru for several years (Anon., 1967a).

Europe: Cyprus—A low-swelling calcium bentonite is mined in the Troulli district near Kambia (Anon., 1969l). A few thousand tons are produced annually. Part is processed in a small plant at Vassiliko, and part is shipped to Israel for beneficiation and use in several products (Anon., 1970e).

Czechoslovakia—Bentonite occurs in the northwestern, central, and eastern parts of Czechoslovakia (Gregor, 1967). The bentonite is chiefly of the calcium and magnesium types, and it formed from rhyolite tuffs. It is as much as 70% montmorillonite; the nonclay minerals present include cristobalite. Bentonite reserves in Czechoslovakia were estimated to be 10 million tons.

Apparently, the most productive bentonite district is in the northwestern part of the country, inasmuch as a bentonite processing plant having a yearly capacity of 91 kt (100,000 tons) was built at Zelenice (Anon., 1969l). One-third of the bentonite produced in this plant is reported to be available for export.

France—The company Société Française des Bentonites et Dérivés SarL. markets several grades of bentonite, mined principally in central France (Anon., 1969j). The deposits mined are presumably those in the Department of Vienne and the Limousin region that have been worked for many years (Dérivière and Esme, 1943). Other bentonite and fuller's earth deposits are in Vaucluse (Mormoiron, Sainte-Radegonde, and Apt) and Pyrénées. Most bentonite and fuller's earth deposits in France are chiefly smectite, but those at Mormoiron are mixtures of smectite and palygorskite (Milot, 1964).

Greece—Rather extensive deposits of bentonite occur in the eastern part of the island of Milos (Anon., 1969l). The deposits are as much as 30 m (100 ft) thick. Apparently they formed by the alteration of ash or tuffs of Pliocene age in a marine environment (Wetzelstein, 1972). One plant near deep water operated by the Greek company, Silver and Barytes Ores Mining Co., has a yearly capacity of 181 kt (200,000 tons). Three other companies are also mining bentonite on this island (Wayland, 1971). The bentonite producers on Milos have been particularly successful in selling bentonite for iron-ore pelletizing, mainly because of the nearness of deposits to deep-water shipping. Bentonite produced on this island is also sold for drilling mud and foundry-sand bond, and for other purposes.

In addition to the deposits on Milos, bentonite also occurs on Mikonos where three companies have been active in recent years. With production on both islands, Greece ranks among the leading producers of bentonite.

Hungary—Bentonite occurs at scattered localities in Hungary. Recently, bentonite-processing facilities were concentrated at Mod, under the supervision of personnel of the National Ore and Mineral Mining Enterprise (Sondermayer, 1967).

Italy—Italy is one of the leading European bentonite producers. The deposits mined are on the island of Ponza, off the western coast, and on Sardinia.

Poland—Bentonite deposits of Eocene and Miocene age occur in southern Poland; these are processed for use as bleaching clay (Nowacki and Ciechomska, 1964) and probably for other uses.

Romania—Romania has been one of the major East European bentonite-producing countries for several years. The bentonite is mined underground in the Alba-Iulia-Ocana Mures district (Neașu, 1969), and apparently it is produced elsewhere.

Spain—Bentonite and fuller's earth occur at several places in Spain. The most productive bentonite deposits are in the Cabo de Gata region in Almería. Fuller's earth deposits consisting mainly of sepiolite occur at Vallecás and elsewhere in the Tagus basin (Anon., 1972b; Huertas, et al., 1971).

Switzerland—Bentonite is mined in Switzerland and used in bonding foundry sands (Grim, 1962).

United Kingdom—Calcium montmorillonite clays occur at many places in the United Kingdom, and fuller's earth has been mined since the Roman period nearly 2000 years ago (Anon., 1969f). Fuller's earth districts now active are at Redhill in Surrey, Combe Hay south of Bath in Somerset, and Woburn in Bedfordshire. In addition to these districts, large deposits of calcium montmorillonite have been discov-

ered in the Swindon-Abington district in Berkshire by the Institute of Geological Sciences (Poole and Kelk, 1971; Poole, et al., 1971), and other deposits occur near Clophill in Bedfordshire, and Maidstone in Kent.

USSR—The principal bentonite deposits in the USSR are in the Volga Region, western and central parts of the Ukraine, Transcaucasia Region, Kazakhstan, and Central Asia (Lebedinskii and Kirichenko, 1972; Anon., 1970a). Smaller bentonite resources also occur in eastern and western Siberia, Crimea, and in the northern Caucasus.

West Germany—Lower Bavaria has been a major producer of smectitic fuller's earth and bentonite for many years. The two major producers are Süd Chemie AG, which has a plant at Mooseberg (Anon., 1969k), and Erbslöh and Co., which operates a plant at Landshut (Anon., 1969e). The deposits are mined mainly by open pit methods, but some underground mining is still done. Both companies produce sodium-exchanged bentonite for use in foundry-sand bonding and for use in several products requiring colloidal properties. Smectite clays are also acid activated and exported to several countries for processing oils and waxes.

Yugoslavia—Calcium-type bentonite occurs in many places in Yugoslavia, and the total resources in the country are very large (Anon., 1969m). The bentonite is processed, including some sodium exchanging, at several places.

The best quality bentonite in Yugoslavia is in the Ginovci deposits, 81 km northeast of Skopje (Konta, et al., 1971).

Africa: Algeria—Calcium-type bentonite is mined in the Marnia and Mostaganem districts of Algeria (Anon., 1969l). Algerian bentonite production in recent years has ranged from 23 to 34 kt/a (25,000 to 38,000 tpy).

Kenya—Bentonite in the Athi River valley has been mined intermittently for use as foundry-sand bonding (Thompson, 1952).

Malagasy—Bentonite is produced on a small scale in this country, inasmuch as 90 t (99 tons) were reported to have been exported from that country in 1969 (Anon., 1969c).

Morocco—Extensive deposits of bentonite occur in the Camp Bertheaux district and other localities near Taourirt in eastern Morocco.

Another type of clay consisting mainly of magnesium montmorillonite called *ghassoul* (rhassoul in French) is produced from deposits in the Tamdafelt district in the middle Moulaya valley (Jeannette, 1952; Eyssautier, 1952) and sold for several uses requiring absorbent clay.

Mozambique—A bentonite processing plant near Impamputo having a capacity of 22 to 24 t/d (24 to 26 tpd) began production in 1963. High-quality bentonite also has been produced at Lourenço Marques in recent years, and some of it is marketed in Europe (Anon., 1973a).

Senegal—Large fuller's earth deposits consisting principally of palygorskite (attapulgitite) occur in the Pout region and elsewhere in Senegal (Wirth, 1968).

South Africa—Bentonite is mined in Transvaal and Orange Free State, and it is reported to have been discovered near Plettenberg Bay, Cape Province (Anon., 1972j; Woodmansee and Murchison, 1969). Production has increased in recent years and now virtually all of South Africa's bentonite requirements are fulfilled by the domestic output.

Tanganyika—The production of a few tons of bentonite in Tanganyika in 1958 was reported by Ross (1964).

Tanzania—Slatick (1969) noted the production of 184 t (203 tons) of bentonite in Tanzania and small quantities mined in other years.

Asia: India—Major fuller's earth deposits occur in at least five states in India, and bentonite occurs at several

localities. Probably the best known deposits are in the Barmer district, Rajasthan (Siddique and Bahl, 1965). They are believed to be transported clays deposited in a marine embayment during late Tertiary time, and the clay minerals formed by the weathering of igneous rock. Other deposits occur in Tertiary beds in Gujarat and in Miocene rocks in Jammu and Kashmir; those in Madras and Bihar are of Jurassic age. Fuller's earth mined in the Mudh district is of Eocene age, and it is chiefly palygorskite (Siddique, 1968).

Japan—Two rather distinct types of smectite mineral deposits occur in Japan (Takeshi and Kato, 1969); one is called bentonite and the other, acid clay. The bentonite is composed chiefly of sodium montmorillonite, and the acid clay is montmorillonite in which H^+ has substituted for exchangeable Mg^{++} and Ca^{++} . Deposits of both types occur at several places in Japan. Bentonite altered from bedded rocks called *Green Tuff* of Miocene age occur in Hokkaido and several places in Honshu (Takeshi and Kato, 1969; Urasima, et al., 1966). Large deposits formed by hydrothermal alteration of rhyolite and rhyolitic tuffs occur in Higashikambara-gun district, Niigata Prefecture (Takeshi, 1963). The Teikoku deposit, one of several in this district, is principally sodium montmorillonite. Bentonite formed by diagenic alteration of tuff beds occurs at Usui-gun, Gunma Prefecture, and several places in Yamagata Prefecture (Takeshi and Kato, 1969; Omori, et al., 1961). Several of these deposits contain appreciable quantities of zeolite, cristobalite, and detrital minerals, which contaminate the montmorillonite.

Large deposits of acid clay formed by diagenic processes occur at Tsuruoka-shi district, Yamagata Prefecture, at Kitakanbara-gun, Niigata Prefecture, and elsewhere. Acid clay formed hydrothermally also occurs at several places in Niigata.

Pakistan—Bentonite occurs at several places in Pakistan. Deposits in the Bhimber district of Azad Kashmir of probable middle Pliocene age have been mined since 1958 (Ali and Shahn, 1962). The bentonite is used for several purposes, including the preparation of surgical dressings.

South Korea—The Dong Bo Clay Industrial Co. operates a bentonite plant in Seoul (Anon., 1973a). The mines are located in North Kyongsang Province.

Turkey—Bentonite and fuller's earth occur at several places in Turkey. Bentonite has been produced on a small scale for domestic use as foundry-sand bond, wine purification, insecticide carriers, and other uses for several years. In 1973, plans were underway for expansion of mining and processing of sodium bentonite (Anon., 1973). Fuller's earth presumably has been used locally for centuries.

The older productive deposits apparently are at Killik, Eskişehir Province, and Kursunlu and Küçük, Çankiri Province (Anon., 1965). The sodium bentonite is near Resadiye, Tokat (Anon., 1973).

Oceania: Australia—A few hundred tons of bentonite have been produced in Australia in recent years (Kalix, 1971), and there has been intermittent mining of fuller's earth for a long time.

The bentonite was produced from Nanango Mineral Field and Ipswich in Queensland, and from lake deposits at Marahagee and Woodanilling in the southwestern part of Western Australia. Fuller's earth was mined on a small scale in the Dubbo district, New South Wales, as recently as 1969.

New Zealand—Bentonite mining began in New Zealand at Porangahau, Hawke's Bay, in 1940, and in recent years it has also been produced in the Harper Hills region of Canterbury.

Evaluation of Deposits

Exploration: The exploration for bentonite and fuller's earth deposits, as for virtually all minerals, requires first an understanding of the geologic occurrence of deposits, then sampling, testing, and appraising of results. An understanding of the geology of the deposits is essential in the early stages and is gained by first reviewing all published and other information on deposits under consideration or on similar rocks in the region. The second step is geologic field investigations, which may require mapping, but reconnaissance studies have been adequate for many deposits. The Wyoming bentonite beds are generally easy to find in the field, because of their tendency to swell when wet and to develop a "popcorn" or frothy texture caused by shrinkage when drying. The calcium or low-swelling bentonite and some fuller's earth deposits are not as easy to find as the swelling-type bentonite, and extensive drilling is commonly required.

Once located, deposits are explored by augering or drilling. The auger method has been widely used for bentonite, mainly because the overlying rocks can be penetrated by such equipment and the bentonite sampled satisfactorily, particularly if the hole is cleaned when the top of the bentonite is reached. Power augers are also used in some fuller's earth exploration, but they have generally been found to be unsatisfactory in searching for palygorskite (attapulgitite) type deposits. These deposits are commonly explored with drilling equipment, and a fishtail bit is used to penetrate the soft sandy overburden, the cuttings being flushed with water. A core barrel with a toothed cutting head is used when the top of the clay is approached, and the clay is sampled with such equipment. A double-tubed barrel has been found to be effective in obtaining more complete recovery in some deposits. Core drilling is also used in exploring for hectorite, because of hard rock in the overburden.

KAOLIN, BALL CLAY, HALLOYSITE, AND REFRACTORY CLAY

Definitions and Classifications

Kaolin: The name kaolin is derived from the Chinese term *Kauling* meaning high ridge, the name for a hill near Jauchau Fu, China, where the clay was mined centuries ago. Apparently the first to use the name kaolinite for the mineral of kaolin were Johnson and Blake (1867). The term kaolin is now variously used as a clay-mineral group, a rock term (consisting of more than one mineral), an industrial mineral commodity, and interchangeably with the term china clay. The following mineralogical definition by Ross and Kerr (1931) is probably the most widely accepted one.

By kaolin is understood the rock mass which is composed essentially of a clay material that is low in iron and usually white or nearly white in color. The kaolin-forming clays are hydrous aluminum silicates of approximately the composition $2H_2O \cdot Al_2O_3 \cdot 2SiO_2$, and it is believed that other bases if present represent impurities or adsorbed materials. Kaolinite is the mineral that characterizes most kaolins, but it and other kaolin minerals may also occur to a greater or lesser extent in clays and other rocks that are too heterogeneous to be called kaolin.

When applied as a term for an economic clay commodity, the foregoing definition must be modified to include some indication of use and to account for the fact that most kaolin now marketed is beneficiated to improve purity and white-

ness. The following definition will apply to further discussions of kaolin in this chapter. Kaolin is a clay consisting of substantially pure kaolinite, or related clay minerals, that is naturally or can be beneficiated to be white or nearly white, will fire white or nearly white, and is amenable to beneficiation by known methods to make it suitable for use in whiteware, paper, rubber, paint, and similar uses. The term is applied without direct relation to purity of deposits. Many very large kaolin deposits are essentially pure, and they require little concentration during preparation for market. Most are slightly off-color and require bleaching, and others contain as little as 10% clay that must be washed and concentrated to recover marketable kaolin.

China clay is an ancient term originating from the use of clay, later found to be kaolinitic, in porcelain tableware and art objects in China. This term will be used rarely in this chapter.

Ball Clay: *Ball clay* is a term apparently originating in the United Kingdom many decades ago from the mining practice of prying out a lump of clay, rolling it into a crude ball, and loading it into a horse-drawn cart or wagon. Ball clay is defined by the American Society for Testing & Materials (Anon., 1971a) as a secondary clay commonly characterized by the presence of organic matter, high plasticity, high dry strength, long vitrification range, and a light color when fired. Kaolinite is the principal mineral constituent of ball clay, and it typically makes up more than 70% of this type of clay. The minor differences between the light fired color required by this definition and the white required for kaolin provide little practical basis for distinguishing these two types of clay. Therefore, ball clay is actually a variety of kaolin, but it is treated as a separate type of clay because of its wide application in marketing and as a use term in the ceramic industries.

The term ball clay is used in the United States, United Kingdom, India, Republic of South Africa, and a few other countries. Similar clay or clay used in the same products as ball clay is included with kaolin or china clay in most countries.

Halloysite: Halloysite occurs in two forms; one has the composition $(\text{OH})_2\text{Si}_4\text{Al}_4\text{O}_{10} \cdot 4\text{H}_2\text{O}$ and the other $(\text{OH})_2\text{Si}_4\text{Al}_4\text{O}_{10}$. The hydrated form is generally a dense porcelainlike hard clay that dehydrates at surface temperatures or slightly above to a white or light-colored porous, friable, or almost cottony-textured material. The dehydrated form is similar to kaolinite in composition and mineral structure, and the hydrated form has a *c*-axis spacing greater than that of kaolinite. The two forms of halloysite have caused considerable nomenclature problems. The system most commonly used now is to restrict the name *halloysite* to the hydrated form and to call the dehydrated form *metahalloysite*. However, some reports use the name *endellite* for the hydrated form and the name *halloysite* for the dehydrated form. As virtually all this clay below the surface occurs in the hydrated form, only the name *halloysite* will be used further in this section, except in the mineralogy discussion.

Halloysite, like ball clay, is a variety of kaolin, and it is included with kaolin in most production statistics. However, the term halloysite is accepted worldwide, and it is used in the clay industries, as well as by mineralogists, geologists, and soil scientists.

Refractory Clay: Refractory clay includes several varieties of kaolinitic clay that are used in the manufacture of products requiring resistance to high temperatures. The qualities and properties of refractory clays are expressed in terms of pyrometric cone equivalents (PCE) which is a method of

designating fusion points. Pyrometric cone equivalent is defined as the number of that standard cone whose tip would touch the supporting plaque simultaneously with that of a cone of the material being investigated, when tested in accordance with the Standard Method of Test for Pyrometric Cone Equivalent (PCE) of refractory materials (ASTM Designation C24) of the American Society for Testing & Materials.

The fusion points of products made from refractory clays range from just above PCE 19, the lower cutoff according to accepted definitions (Norton, 1968), to as high as cone 37. The refractory properties of kaolinitic clays are ordinarily classified, according to suitability for heat service, as low (PCE 19 to 26), moderate (PCE 26 to 31½), high (PCE 31½ to 33), and superduty (PCE 33 to 34). A few essentially pure kaolinite clays have fusion points as high as cone 35, and some refractory kaolins and fire clays containing diaspore, boehmite, or gibbsite have PCE's as high as cone 37.

The principal types of clay included in the refractory clay are fire clay, kaolin, and ball clay. Definitions of refractory kaolin and refractory ball clay are the same as given for these two types of foregoing definitions, except that the adjective "refractory" is added to indicate use. The definition of fire clay used in this chapter is essentially the one by Norton (1968), which assigns this term to all clays that are not white burning and have a PCE above 19. The term *fire clay*, therefore, excludes most kaolin and ball clay because they burn white, but it does include kaolin and ball clay that are colored when fired. This classification of refractory clay as a group name and the threefold subdivision are by no means universally applied. Other reports, including earlier ones by the authors themselves, have used the terms *refractory* and *fire clay* interchangeably.

Kaolin

History and Uses: The sedimentary kaolins of the Coastal Plain of Georgia and South Carolina and the residual kaolins of North Carolina have been known since Colonial times. Smith (1929) quotes from Sholes in his chronological history of Savannah, "1741—Porcelain Clay was discovered in or near Savannah by Mr. Duchet, and china cups made." In 1767, Josiah Wedgwood sent Thomas Griffiths to Macon County, North Carolina, to send a shipment of china clay to England (Goff, 1959). Minton (1922) recorded that, "As early as 1766 American clays from Georgia, Florida, and the Carolinas were being sent to England in considerable quantities." These clays were regularly imported and used by Wedgwood until the clays of England were available. In 1768 (Barton, 1966), the English kaolins in Cornwall were discovered, which virtually ended the mining of the Georgia kaolins for more than a century. In 1876 (Smith, 1929), the mining of the sedimentary kaolins of Georgia was started again by Riverside Mills of Augusta in Richmond County. Mining of the Georgia kaolins has been continuous since that time. In addition to the original pottery in Savannah, a second pottery was established near Bath, Aiken County, SC, at an early date. This plant was destroyed during Sherman's march to the sea (Lang, et al., 1940). However, kaolin mining was active again in Aiken County shortly after the Civil War and has continued with only minor interruptions until the present. South Carolina has ranked as the second leading kaolin-producing state for several decades. Kaolin mining in North Carolina started in 1888 in Jackson County (Parker, 1946), and in 1904, the earliest mines opened in the Spruce Pine district. The first kaolin operation in Vermont (Ogden, 1969) was in the early 1800s, and most of the product was sold in Troy and Albany, NY.

Kaolin has many industrial applications (Murray, 1963a), and new uses are still being discovered. It is a unique industrial mineral because it is chemically inert over a relatively wide pH range, is white, has good covering or hiding power when used as a pigment or extender in coated films and filling applications, is soft and nonabrasive, has low conductivity of heat and electricity, and costs less than most materials with which it competes. Some uses of kaolin require very rigid specifications including particle-size distribution, color and brightness, and viscosity, whereas other uses require practically no specifications; for example, in cement, where the chemical composition is most important. The better grades of kaolin make up most of the tonnage sold and, of course, have the highest value. Many grades of kaolin are specially designed for specific uses, in particular for paper, paint, rubber, plastics, and ceramics.

Geology: Mineralogy—By definitions, the clays discussed in this section consist chiefly of kaolin-group minerals. The members of this group are kaolinite, nacrite, dickite, and halloysite. With the exception of the hydrated form of halloysite, which has somewhat more water, all these minerals have essentially the same composition. Their overall crystal structures are also similar, but minor differences in arrangements of ions in octahedral positions, stacking of unit layers, crystal habit, etc., are sufficient to cause the use of separate names. Kaolinite is, of course, the most common member of the group, and halloysite obviously forms halloysite deposits. The other two members of the group rarely occur in economic deposits.

Structurally, kaolinite consists of an alumina octahedral sheet and a silica tetrahedral sheet. These sheets form triclinic crystals. The theoretical structure formula of kaolinite is $(\text{OH})_2\text{Si}_4\text{Al}_4\text{O}_{10}$, and the theoretical composition is SiO_2 46.54%, Al_2O_3 39.5%, and H_2O 13.96%. There is relatively little ionic substitution in the mineral lattice, although there is evidence suggesting minor substitution of iron for aluminum in some kaolinite. The perfection or degree of ordering of kaolinite crystals varies considerably. By interpretation of X-ray diffraction data, Murray and Lyons (1956) have shown that the crystallinity of Georgia kaolin ranges from poorly ordered to very well ordered forms. Other investigators (Brindley and Robinson, 1946; Range, et al., 1969) have found similar variations in ordering in kaolinite from several localities. The more perfectly ordered forms of kaolinite commonly occur in hexagonal or subhexagonal crystals. Growths of crystals along the *c*-axis into accordionlike or vermicular forms are also common.

The clays described in this section contain, in their natural occurrence, a wide variety of mineral impurities. Georgia kaolin generally is 85 to 95% kaolinite, the remainder is mainly quartz, minor muscovite, biotite, smectite, ilmenite, anatase, rutile, leucosene, goethite, and traces of zircon, tourmaline, kyanite, and graphite. Kaolin deposits in Latah County, Idaho, contain considerable ilmenite (Hosterman, et al., 1960). Kaolinite and halloysite make up from 10 to 40% of residual deposits in the Spruce Pine district, North Carolina. The bulk of these deposits consists of angular quartz, muscovite, microcline, and partly altered plagioclase (Parker, 1946). The well-known English kaolins, which are 10 to 40% kaolinite, consist mainly of quartz, mica, and potash feldspar; tourmaline is also present (Bristow, 1969).

Occurrence—Most kaolin is soft and plastic when natural moisture is present or where water has been added to dried material. One way of describing the natural texture is by the colloquial phrase—a good whittling clay—which refers to the ease with which the clay can be carved with a knife. Dry

kaolin is ordinarily friable, and a common but not a diagnostic test for it is its stickiness when touched to the tongue. Some types of kaolin, which have apparently been under considerable overburden or which contain introduced silica, are hard and are sometimes referred to as flint kaolin. Though much more lithified than plastic varieties, this so-called flint kaolin is softer than most flint clay referred to in the section on fire clay, which also consists of kaolinite.

Kaolin and related clays occur in several different types of deposits. Many kaolin deposits throughout the world are in the form of tabular lenses and discontinuous beds in sedimentary rock. Most deposits of this type are of Cretaceous age or younger. The shapes and lateral extent of such deposits vary appreciably. Deposits as much as 18 m (60 ft) thick are common in some districts, and bodies of kaolin are known to extend laterally for more than a mile. Extensive sedimentary deposits of this type occur in the Georgia-South Carolina kaolin belt (Anon., 1970i), Arkansas bauxite region (Gordon, et al., 1958), and Ione district, California (Johnson and Ricker, 1948).

Residual kaolin deposits occur in weathered rock, and they are at or very near the surface, except where they formed during ancient weathering cycles and were later buried by younger rocks. Most residual kaolin deposits have formed from igneous rock. The age of kaolin formation is commonly controlled by the age of the present land surface rather than the age of the parent rock. Residual kaolin deposits are generally irregularly shaped and grade downward into the parent rock through partly altered weathered saprolite zones. They also commonly contain rounded boulders and irregular masses of fresh or only partly altered rock that were originally in the centers of joint blocks or otherwise protected from percolating water. Residual kaolin deposits occur in the Spruce Pine district, North Carolina (Parker, 1946); the Arkansas bauxite district (Gordon, et al., 1958); Latah County, Idaho (Ponder and Keller, 1960); Alberhill district, California (Cleveland, 1957); and elsewhere in the United States. They also occur in many other countries and are particularly common in Czechoslovakia (Kuzvart, 1969) and Brazil (de Souza Santos and de Souza Santos, 1972).

Some kaolin deposits throughout the world occur in rocks that have been hydrothermally altered. Such deposits are ordinarily in irregularly elongate pods or pipelike bodies aligned along joints, faults, or other permeable zones that allowed movement of warm or hot aqueous solutions. Some deposits of this type also occur in altered tuffs and are bedded. As with the residual type, the age of hydrothermal kaolin formation is not necessarily related to the age of the host rock. Most hydrothermal clay deposits are probably no older than Tertiary, though some occur in rocks that are much older. Insofar as the authors are aware, deposits in the Little Antelope Valley, California (Cleveland, 1957), contain the only hydrothermal kaolin now mined in the United States. It is used for refractory clay. However, kaolin formed by this process occurs at many places in the western states, and deposits were formerly mined on a small scale in several mining districts.

Origin—The two fundamental geologic processes that form most of the clay minerals of the kaolin group are weathering (Keller, 1964) and hydrothermal alteration (Sales and Meyer, 1949). These processes under certain conditions remove elements other than silicon, aluminum, oxygen, and hydrogen, the constituents of these clays. The clays form as the other elements are removed from preexisting minerals and possibly by the growth of new atomic arrangements from materials in solution. Though most kaolin minerals form in

these ways, the origin of valuable deposits is quite another matter. Certainly several commercial clay deposits throughout the world have formed by hydrothermal processes, and others have formed in place by the weathering of other rocks. However, many of the large high-grade deposits of kaolin occur in sedimentary rocks and have either been (1) transported and deposited as kaolin; (2) altered from previously transported rocks by processes related to surficial weathering, submarine or subaqueous alteration, or postburial (diagenetic) changes; or (3) combinations of these possibilities.

Knowledge regarding the origin of kaolin deposits in the United States varies considerably. The origins of some of the deposits are reasonably well established, but geologists have widely differing opinions on how other deposits formed. Clearly, many of the scattered kaolins in western states formed by hydrothermal processes, but few such deposits have been significant sources of kaolin. In the Arkansas bauxite region (Gordon, et al., 1958) and in Latah County, Idaho (Hosterman, et al., 1960), are districts containing both transported clay and residual kaolin formed by weathering of igneous rock. In both districts, the kaolin grades downward through saprolitic zones into parent rock, which is nepheline syenite in Arkansas and granodiorite in Idaho. Also, in both districts, kaolin transported from the residual material occurs in sedimentary rocks—in marine shale in Arkansas and in lacustrine beds in Idaho. However, this explanation of origin is inadequate to account for all the kaolinitic clays in the regions containing these districts. The transported kaolin in Arkansas is of Wilcox age (early Eocene), and kaolinitic clays occurs in rocks of this age throughout a much more extensive region than can be related to the nepheline syenite in Arkansas. Similarly, the Miocene clays in Idaho cannot all be related to granodiorite. Another type of kaolin deposit that is reasonably well understood occurs as sinkhole fillings in the Valley and Ridge province in the eastern part of the United States. This type of kaolin apparently formed by the leaching of other aluminous minerals by downward-moving water in sinkholes. Probably the parent aluminous materials were mainly residuum from the solution of carbonate rock. This explanation is in part based on the presence of cores of gibbsitic bauxite in the centers of such deposits and the enclosing envelopes of cherty clay separating the kaolin from the carbonate rock in the walls of the sinkholes.

Strange as it may seem, the deposits whose origins are least understood include those in the extensive belt in Georgia and South Carolina which have been studied by many geologists and mineralogists and which lead the world as a source of commercial kaolin. Virtually all who have investigated these deposits agree that either the kaolin or the material from which it formed has been transported. Areas of disagreement center about explanations of how such very large deposits of fine-grained white clay could have formed in environments in which some sediments being deposited consisted of sand containing much more iron than does the clay. Furthermore an adequate explanation of origin of the deposits must account for the following facts: (1) some deposits of kaolin are finer grained than others; (2) some contain abundant accordionlike booklets and some do not; (3) gibbsite is present in some deposits and not in others; (4) lignitic layers or layers rich in organic matter are present in some deposits; and (5) smectite is present in some deposits in variable quantities.

One of the first geologic studies of the Georgia kaolin was by Ladd (1898); he described the deposits but did not discuss their origin. Veatch (1909) concluded that the low-

est member of the Cretaceous system, the Tuscaloosa, is the most important clay-bearing formation in Georgia. He indicated that the age of the formation in Georgia was determined only by its stratigraphic position. Veatch believed that the material making up the Tuscaloosa Formation was derived from disintegrated and decomposed rocks of the Piedmont Plateau. The greater part of the Piedmont region was a land surface for a very long period of geologic time. Just before the beginning of the Cretaceous, the Piedmont region was uplifted and tilted southeast. Streams rapidly carried the weathered residue to the Cretaceous sea. Veatch postulated that an enormous quantity of sediment was dumped rapidly at the stream mouths, forming extensive sand flats. Fine clay particles were deposited in nonpersistent and lenticular beds of white clay in the deeper and quieter waters near the stream mouths. He considered the Tuscaloosa in Georgia a nonmarine deposit.

Smith (1929) concluded that the basal Cretaceous sediments in Georgia were Upper Cretaceous and correlated them with the Middendorf Formation of eastern South Carolina. Smith believed that Veatch's explanation of origin was essentially correct, except that he agreed with Neumann (1927) that the kaolin was deposited in saltwater. Cooke (1943) assigned the basal Cretaceous sediments to the Upper Cretaceous under the name Tuscaloosa, which is still used. Kesler (1963) believes that in east-central Georgia there is no basis for subdividing the Upper Cretaceous, and he found that the kaolin lenses have no preferred stratigraphic position within the formation. Kesler theorized that feldspathic sands were deposited as delta sediments above sea level and were subsequently altered to kaolin. The kaolin was separated from the coarser sediment and deposited at points of lowest elevation. As the kaolin accumulated in the ponds, sand was washed from the margin into and over the edge of each deposit, forming gradational and interfingering contacts.

Bates (1964) reviewed the origin of the Georgia kaolins and summarized the mineralogic and geologic data, some of which support a marine origin and some a freshwater origin. Hinckley (1961) suggested that face-to-face flocculation of kaolin particles in a marine environment would result in the properties that distinguish a so-called "hard" kaolin, whereas edge-to-face flocculation in freshwater would produce a less dense, "soft" clay. Buie (1964) proposed the possibility that volcanic ash was first altered to montmorillonite and then to kaolinite. This is a radical departure from previously proposed theories of origin, and much more detailed field and laboratory work must be done before this hypothesis can be adequately tested. Jonas (1964) concluded from a detailed petrologic study that the originally deposited sediment was muscovite, feldspar, and quartz, and that post-depositional alteration and recrystallization produced the kaolin deposits now mined.

Recent studies of spores, pollen, and invertebrate fossils in and associated with kaolin indicate that many of the deposits thought to be Cretaceous are of Eocene age (Buie and Fountain, 1967; Cousminer and Terris, 1972; Scudato, 1969), a possibility suggested by Eargle (1955). The first announcement of the Eocene age for any of the deposits was by Buie and Fountain, who on the basis of paleontological evidence established the presence of middle Eocene strata beneath some of the commercial kaolin deposits and above others. In one of the studies, Cousminer and Terris (1972) concluded through palynological work that some, if not all, of the sedimentary kaolin is middle Eocene in age. Results of palynological studies by R. H. Tschudy of the US Geological Survey on samples collected by Patterson have con-

firmed that some of the kaolin deposits are of Late Cretaceous age or older, and that some are no older than Claiborne (middle Eocene). Tschudy's work also revealed that sand beds of Paleocene age are present in the kaolin belt. This raises the possibility that some of the kaolin deposits may be of Paleocene age and that kaolin deposition took place during several different intervals of geologic time.

The recent findings on the range in age of Georgia kaolin deposits reinforce our opinion that the deposits have had a very complex history and origin, and the theories advanced to date do not provide adequate explanations. Probably the purity of the kaolin is the result of some sedimentary winnowing process, an idea favored by Kesler (1963) and others, as evidence now available suggests that the ultimate source was aluminum silicate minerals in the crystalline rocks to the northwest. The environment in which the deposition took place is yet to be established, but it was probably similar to the present coast of Georgia and South Carolina, where there are abundant offshore sand bars and swampy, muddy lagoons and winding estuaries. How iron was removed from the kaolin remains a problem; removal of iron may have been due mainly to chelating by organic acids from decaying plant materials, and oxidizing pyrite may have contributed to the process. Some of the differences in physical properties of the kaolin may be due to the fact that parts of the deposits, particularly the younger ones, have been reworked. Other differences in physical properties are probably due to varying degrees of diagenetic alteration, as most of the deposits now known to be Cretaceous in age contain more vermicular crystal growths and coarser particles than do the deposits known to be of Eocene age.

Major Kaolin-Producing Countries: *United States*—**GEORGIA-SOUTH CAROLINA KAOLIN BELT.** The principal reserves and the major kaolin-producing centers in the United States are in a belt extending from Twiggs County in the central part of Georgia to Lexington County in west-central South Carolina. This same belt extends southwest from Macon to Andersonville, GA (Zapp, 1965), and west to Eufaula, AL (Warren and Clark, 1965). The Andersonville and Eufaula districts contain appreciable kaolin resources, but both are centers of production of refractory kaolin and refractory bauxitic materials, and no kaolin, as defined in this report, is now produced in either district.

ALABAMA. Kaolin is mined from the Tuscaloosa Group in Marion County, Alabama (Clarke, 1964). It has been mined in this area for 40 years, and approximately 1 million tons has been shipped. This kaolin is relatively pure and is easily beneficiated by removing quartz and mica. Most of the production from this district has gone into various ceramic products.

CALIFORNIA. Filler-type kaolin is mined and processed near Ione and Bishop, CA. The Ione clay is sedimentary in origin (Bates, 1945), whereas the kaolin near Bishop is hydrothermal (Cleveland, 1957).

FLORIDA. The Florida kaolin is found in sand and gravel deposits of the Citronelle Formation (Calver, 1949).

IDAHO. Filler-type kaolin is mined and beneficiated in Latah County, Idaho.

NORTH CAROLINA. Near Spruce Pine, a primary kaolin (the term *primary kaolin* is used here as commonly applied in the kaolin industry for hydrothermal-type deposits and for residual deposits of kaolin formed by in-situ weathering) altered from pegmatite and aplite (Parker, 1946) is mined and beneficiated.

TEXAS. Near Kosse, TX, a kaolin deposit of early Eocene age in the Wilcox Group is mined and beneficiated as a filler

and ceramic clay (Fisher, et al., 1965). Pence (1954) described these deposits as nonmarine in origin. They contain 40 to 70% quartz, and the kaolin is a byproduct of a glass-sand operation.

OTHER STATES. Kaolin has been mined in the past or has been reported present in commercial quantities in Arkansas (Tracey, 1944), Illinois (Grim, 1934), Minnesota (Parham, 1970), Mississippi (Conant, 1965), New Mexico (Glassmire, 1957), Vermont (Ogden, 1969), and Virginia (Ries and Sommers, 1920).

RESOURCES. Resources of kaolin in the United States of a quality equal to or better than the lower grade clay now mined are at least 1 billion tons. The one grade of kaolin about which there is concern for long-range supply is the very high grade fine-particle-size white clay suitable as a paper coater and for certain other specialty uses (Buie, 1972). Reserves of this type of clay probably total 100 to 200 million tons. Potential resources of kaolin, including discolored and very sandy clay and that below more overburden than can be profitably stripped at present, are several times the estimated reserves.

United Kingdom—The United Kingdom is second only to the United States as a producer of kaolin or china clay and is the largest exporter of kaolin in the world (Anon., 1972g). China clay is the United Kingdom's chief export, and almost the entire output comes from the St. Austell area of Cornwall. Historically, the china clays in Cornwall were discovered by William Cookworthy (Barton, 1966) in the mid-1700s to be suitable for making porcelain. In Cornwall, an extensive region of kaolinized granite has been formed by hydrothermal alteration of feldspar (Bristow, 1969). The granite masses were emplaced in Permian time and are now exposed over large areas of Devon and Cornwall. The china clay deposits typically occur in funnel or troughlike bodies narrowing downward. Hot acidic solutions are thought to have migrated upward, guided by structural weaknesses such as faults and joints, and then to have been trapped under a roof of relatively impermeable rock. The hot solutions attacked the granite, altering the feldspar and mica to kaolinite. Quartz, tourmaline, and mica are the principal impurities. Drilling has shown kaolinization to exist at depths of more than 244 m (800 ft) (Bristow, 1969).

USSR—Kaolin is mined and processed in several districts in the USSR (Petrov, 1969). Residual, hydrothermal, and sedimentary deposits are worked. One kaolin deposit in the Transcarpathian region consists of virtually pure dickite (Rusko, 1973), and other deposits in this same district consist of mixtures of kaolinite, dickite, and halloysite. Gluhovetski district, southwest of Kiev, approximately midway between the cities of Zhitomir and Vinitza, is one of the major centers of production. The best grades of kaolin are produced from deposits formed in weathered granite. Another major producing district is in the vicinity of Prosyantovskii in the Dnepropetrovsk region. The deposits in this area also occur in weathered granite and gneiss. Other large kaolin deposits occur in Kazakhstan. The largest sedimentary kaolin is the Pologa deposit on the Konok River near the Pologa Station. Many other kaolin deposits have been described by Petrov (1969). The Russian kaolin is used in the paper, ceramic, rubber, and chemical industries.

Minor Kaolin-Producing Countries: *North America*—**MEXICO.** Most of the kaolin in Mexico is in primary deposits originating by hydrothermal alteration of Tertiary rhyolitic rocks (Pasquera, et al., 1969). The deposits are found in almost every state, but the largest commercial deposits are in the central part of the country.

South America—ARGENTINA. The kaolin production in Argentina in 1969 was 73.4 kt (80,905 tons) (Anon., 1971b). Most of this kaolin was mined in the Blaya Dognac, Don Carlos, and Maruja districts, Chubut. Districts in Rio Negro and San Juan also had active mines in recent years.

BRAZIL. Kaolin deposits in weathered granites, pegmatites, and other crystalline rocks occur at many localities in Brazil, and recently very large transported deposits have been discovered. The deposits in weathered rocks have been mined for domestic use for many years. One region containing significant deposits of transported kaolin is along the Jari River (Colligan, 1973), a tributary of the Amazon. The deposits along this river are of Pliocene age (Klammer, 1971). Another region in which the kaolin deposits are being evaluated is along the Capim River approximately 200 km south of Bélem (White, 1973).

GUYANA. Very large transported kaolin deposits are associated with bauxite in Guyana and Surinam (Moses and Mitchell, 1963). These deposits are in sedimentary rocks underlying the Coastal Plain seaward from a shield area of ancient crystalline rocks.

OTHER COUNTRIES. Both residual and transported kaolin deposits occur at several places in Chile, Colombia, and Venezuela (Malkovský and Vachtl, 1969c). Hydrothermal deposits are also present in Chile, as indicated by the association of kaolin with alunite. Small tonnages of kaolin are also produced in Peru, Paraguay, and Ecuador (Ampian, 1973).

Europe—The kaolin operations in continental Europe are mostly small scale because of the scarcity of high-grade deposits. Most of the kaolin produced is still used by the ceramics industry and as filler for paper, and only minor quantities are sold for other applications. West Germany produces nearly 500,000 tpy kaolin, the main production being from Bavaria. The kaolin deposits in Brittany in France are being worked to a much greater extent, and production from this area will increase substantially. Czechoslovakia, where the production is controlled by the state, is becoming an important producer, and exports kaolin to other European countries.

AUSTRIA. Economically important kaolin deposits of primary origin occur on the *Bohemian Massif*, a deeply eroded complex of granitic and metamorphic rocks (Holzer and Wieden, 1969). Most of this kaolin is used in the ceramic industry and as filler in the paper and rubber industry.

BULGARIA. Sedimentary kaolin deposits of probable Pliocene age occur in northwestern Bulgaria (Karanov, et al., 1969). The individual deposits are small because the kaolin is associated with sand which fills sinkholes in a karst area underlain by Lower Cretaceous limestones.

CZECHOSLOVAKIA. Czechoslovakia is the principal producer of kaolin in Eastern Europe. The major deposits are in the vicinity of Karlovy-Vary, Plzeň (Pilsen), and Podborany in west Bohemia (Kuzvart, 1969). The kaolin is primary, is of high quality, and is used for the production of fine ceramics, paper, rubber, and refractories.

DENMARK. A small tonnage of primary kaolin is mined on the Island of Bornholm primarily for the Danish ceramic industry in Copenhagen (Almeborg, et al., 1969).

EAST GERMANY. Both primary and secondary kaolin deposits are worked in East Germany (Störr, et al., 1969). The kaolin is mined from an area north of Bautzen, Dresden, and Colditz.

FRANCE. Many small companies produce kaolin from districts in Brittany and around the Massif Central in central France. The deposits in Brittany are of approximately the

same age as those in Devon and Cornwall in England (Anon., 1972f). In Brittany, the deposits are all primary in origin; and the deposits around the Massif Central are both primary and secondary (Damiani and Trautmann, 1969). About 80% of the French production is from Brittany and is near the coast.

GREECE. Low-grade deposits of kaolin suitable for use in cement, ceramics, refractories, and paper filler occur on the Aegean islands of Milos, Polyaeos, and Mytilene (Anon., 1972f). Reserves are small and production is limited.

HUNGARY. Most of the commercial kaolin deposits in Hungary are confined to an area in the northeast, in the Tokaj Mountains. These deposits are primary and have been derived from rhyolite (Varju, 1969). Secondary kaolin-bearing sandstones are mined and washed at Sarisap in the Visegrad Mountains west of Budapest.

ITALY. Both primary and secondary kaolin deposits are mined in Italy, primarily for the ceramic industry. Production is small and has never reached 90,000 tpy (Moretti and Pieruccini, 1969). The most important areas are in northwest Italy near Brella, on southern Sardinia, and near Rome.

POLAND. In the Lower Silesia area of Poland southwest of Wrocław, primary kaolin derived from granite and gneiss is mined for local consumption mainly for the ceramic industry (Anon., 1970h; Gawronski and Kozydra, 1969).

SPAIN. Spain has the fourth largest production of kaolin in Western Europe (Anon., 1972f). Both primary and secondary deposits are mined in Spain. The deposits are widely scattered, but the commercially important production is concentrated in the northwest near Galicia-Asturias and in the east near Cuenca-Teruel-Valencia. The primary deposits of Galicia were formed by the hydrothermal alteration of mylonitized granite; reserves exceed 300 million tons. The secondary deposits in eastern Spain are Cretaceous in age and are principally kaolinitic.

WEST GERMANY. The largest kaolin mining district is in the townships of Hirschau and Schnaittenbach in Bavaria (Anon., 1972f). The deposits are sedimentary in origin, derived from decomposed granite in the Naab basin mountains, and are Triassic in age. These deposits consist of a mixture of quartz, feldspar, and kaolin. Other areas in West Germany where kaolin is worked are Oberneisen near Frankfurt, Hesse, and Westphalia (Lippert, et al., 1969).

OTHER COUNTRIES. Small tonnages of kaolin are produced in Romania, Sweden, Portugal, Yugoslavia, and Belgium (Ampian, 1973; Malkovský and Vachtl, 1969b).

Africa —REPUBLIC OF SOUTH AFRICA—The kaolin deposits of South Africa have been derived from the weathering of granite, shale, and tillite (Coetzee, 1969). Kaolin is mined near Capetown, Grahamstown, and Durban. With the exception of the large deposit of altered tillite near Grahamstown (Murray and Smith, 1973), deposits are small but of good color and quality. The Grahamstown deposit is very large, with reserves in excess of 50 million tons, but the quality ranges from excellent to very poor and it changes in very short intervals both horizontally and vertically.

SWAZILAND. Kaolin deposits of economic importance are found in the Malilangatsha Mountains of the Manzini district (Hunter and Urie, 1969).

OTHER COUNTRIES. Other African countries having minor kaolin production include Angola, Arab Republic of Egypt, Ethiopia, Kenya, Nigeria, Tanzania, Malagasy, Mozambique, and Morocco (Ampian, 1973; Malkovský and Vachtl, 1969c). The deposits in the Pugu Hills district near Dar es Salaam, Tanzania, are among those having economic potential.

Asia—SRI LANKA—The best known kaolin deposit on Sri Lanka is the Boralessgamuwa field, south of Colombo. The kaolin is probably Pliocene or Pleistocene in age (Pattiaratchi, 1969).

INDIA. Kaolin and related clay materials are mined in many locations in India (Arogyaswamy, 1968). The major producing area is in the vicinity of Chaibasa. The deposit mined in this district occurs in weathered granite. High-quality kaolin is also produced in the vicinity of Kundra, Chhannur, and Quilon, Kerala.

INDONESIA. Large residual kaolin deposits altered from granite are known to occur on the islands of Belitung and Banka (private communication). Although the deposits are large, little is known about the quality of the kaolin.

IRAN. The largest kaolin deposit in Iran is in the central part of the country near Simiron (Khadem, 1969).

JAPAN. Large primary and secondary kaolin deposits occur in Japan (Fuji, et al., 1969). The deposits are scattered throughout the islands. The primary deposits were formed by hydrothermal alteration of volcanic and granitic complexes and from in-situ weathering of granite, pegmatite, and volcanic rock. The secondary deposits are lacustrine, of lower Pliocene age.

KOREA. Primary and secondary kaolins occur in Korea (Heikes and Kim, 1965). The largest deposits, consisting of mixtures of kaolinite and halloysite, are in the Hadong-Sanchong area of southernmost Korea.

MALAYSIA. Residual kaolin altered from granite is being mined (Anon., 1970f) east of Kuala Lumpur.

PEOPLES REPUBLIC OF CHINA. Kaolin not only was used first in China, but advertisements in recent trade journals indicate that it is still being mined on a large scale and is available for export. Historically, deposits in the Ching-Tae-Chen district in Fuliang, Kiangsi Province, were the principal source of kaolin used in making fine ceramic ware (Pai, 1945). Other kaolin-producing regions in China include Singtze, Loping, Yukan, and other districts in Kiangsi Province, and Tzuhsien, Kaiping, Fengyn, and Chinghsing, Hopeh Province. Kaolin in deeply weathered granite occurs at several localities in Kwangtung Province which surrounds Hong Kong. Kaolinite clays associated with diaspore and bauxitic clays in Carboniferous, Permian, and Mesozoic coal measures occur in Szechuan, Honan, Kupeh, and Fukian Provinces and elsewhere. Residual kaolin formed by the weathering of arkosic sandstone occurs in Szechuan Province, and deposits formed from weathered feldspar in granite and pegmatite occur at several places in China.

PHILIPPINES. Philippine kaolin deposits are primary and are generally small and scattered. Most are hydrothermal in origin, although one deposit called Bukidnon is believed to have formed from in-situ weathering of a dacite (Comsti, 1969). The major deposits are on Luzon and Mindanao.

TURKEY. Both primary and secondary kaolin deposits are mined in Turkey, primarily for the Turkish ceramic industry.

OTHER COUNTRIES. The production of kaolin has been reported in recent years (Ampian, 1973) in Pakistan, Taiwan, Thailand, and South Vietnam.

Oceania—AUSTRALIA—Most of the kaolin deposits in Australia are primary and have been formed as a result of deep weathering of both silicic and mafic rocks (Gaskin, 1969). Secondary deposits in Western Australia are associated with the coal measures of Cretaceous age. Most of the deposits mined are within 200 km of the major cities of Melbourne, Sydney, Adelaide, and Perth. Extensive exploration for kaolin is being carried out in Australia by several

major companies, primarily because of the lucrative Japanese export market.

NEW ZEALAND. The only kaolin being produced in New Zealand at present is in the Northland some 120 km north of Auckland (Bowen, 1969).

Exploration, Evaluation

Exploration in the United States: The principal productive deposits of kaolin were found in the Carolinas and Georgia in the late 19th and early 20th centuries. Most discoveries were in outcrops in stream beds and road cuts. Today, exploration is carried out in geologically favorable areas, taking into account topography and elevation. Geologic and topographic maps, if available, and aerial photographs are used to lay out exploration drill-hole patterns. Most exploration holes are drilled to depths of as much as 61 m (200 ft) and on 122- to 244-m (400- to 800-ft) centers. Many deposits were missed in the past because only random spot drilling instead of pattern drilling was used. Also, because drilling was limited to 15 or 18 m (50 or 60 ft), many good deposits at greater depths were not discovered. Auger or fishtail drills are used to the top of the kaolin bed, and then a special core barrel is used to core the kaolin. Cores are difficult to recover, and special care by expert drillers is necessary to get good core recovery. In many areas, two or three kaolin beds separated by sand are penetrated where drilling is as deep as 61 m (200 ft).

Many geophysical methods of exploration for kaolin have been attempted, but to date none has been successful (Gross, 1960). Geochemical techniques also have been unsuccessful. The only positive method to locate and delineate kaolin deposits to date is by pattern drilling.

Evaluation of Deposits: After coring the kaolin and recording the thickness of the various strata above the kaolin and the thickness of the kaolin bed, a large-scale map is prepared. On this map, the drill holes are located and the thickness of the overburden and the kaolin are recorded. The cores are sent to the crude evaluation laboratory where the kaolin is prepared and tested for (1) percent grit or screen residue, (2) particle-size distribution, (3) low shear viscosity, (4) high shear viscosity, (5) brightness, and (6) leachability.

After all the tests are performed and evaluated and the overburden thicknesses and the thicknesses of the deposit have been determined, a decision is made whether the deposit is of a quality suitable for any of the present uses for kaolin or a potential aluminum resource, or whether the property should be dropped. The economic limits of the ratio of overburden to kaolin that can be mined economically range between 6 and 8 to 1, depending on the type of overburden, and the reclamation requirements imposed by federal and/or state law.

If the decision is made to keep the deposit for future mining, then additional drilling is done on 61- or 30.5-m (200- or 100-ft) centers. From this drilling information, additional maps and cross sections are prepared, from which a stripping and mining plan is devised.

The classification of a deposit as potential aluminum clay is of relatively recent practice as a result of the interest in using kaolin as a raw material to produce aluminum. The United States is dependent on foreign sources of bauxite supply approximately 90% of its aluminum requirements. The purchase of bauxite represents a significant outlay of dollars which contributes to our balance of payment deficits. Kaolin clays in Georgia and South Carolina contain 35 to 39% Al_2O_3 and represent a very sizable resource from which

aluminum could be recovered if the economics become favorable.

Ball Clay

History and Uses: Probably the first deposits of the material now known as ball clay mined in the United States were those worked near Paris, TN, in 1860 for use in a local pottery (Hosterman, 1973). The first clay shipped to out-of-state consumers was that produced in west Tennessee in 1894 by a Mr. I. Mandle. Later, the industry expanded into Kentucky, and the ball clay districts in the western parts of these two states competed with districts in the United Kingdom (Anon., 1969d) for the world leadership in production. More than 80% of the ball clay tonnage produced is by companies active in Tennessee and Kentucky. The other states producing ball clay are Mississippi, Texas, and California. Ball clay is also produced intermittently in Maryland.

Ball clay is used principally in the manufacture of vitreous china sanitary ware, electrical porcelain, floor and wall tile, dinnerware, and artware (Phelps, 1972). It is also used in refractory products, ceramic glazes, and porcelain enamel slips.

Geology: Mineralogy—Kaolinite is the principal mineral in the ball clay deposits in Tennessee and Kentucky, but other clay minerals are present and nonclay minerals vary appreciably in abundance. The kaolinite in these deposits is fine-grained, and much of it is poorly ordered. The main clay minerals other than kaolin are illite, smectite, chlorite, and mixed-layer clay. Quartz is by far the most abundant nonclay mineral; in some deposits it makes up as little as 5% of the clay, but in others, as much as 30% (Olive and Finch, 1969). The other nonclay minerals ordinarily present occur in very minor or trace amounts and include plagioclase, potassium feldspar, and calcite. Organic matter in the form of black leaf imprints and disseminated lignitic and peaty materials are common in most ball clays.

Occurrence and Origin—Ball clay is extremely plastic. Deposits range from very light gray to nearly black. Most deposits are lenticular bodies varying considerably in size and shape. Some are more than 9 m (30 ft) thick and extend over areas 305 m (1000 ft) wide and 762 m (2500 ft) long, but most deposits are smaller. The physical properties of a typical deposit vary considerably, and layers and pockets mined from a given deposit are commonly separated in different stockpiles suitable for a particular use.

Most deposits in Tennessee and Kentucky are in beds of Claiborne age (middle Eocene), but a few, including one mined, are in Wilcox beds (lower Eocene) (Olive and Finch, 1969). The deposits mined in Texas near Henry's Chapel, northeastern Cherokee County (Fisher, et al., 1965) are also in Wilcox beds. The ball clay mined in Panola County, Mississippi (Bicker, 1970), is in a formation of Claiborne age, and the deposits are approximately the same age as younger ones in Tennessee and Kentucky. The deposits mined in Stanislaus County, California, are in beds of Paleocene or Eocene age (Cleveland, 1957). Those mined on a small scale in the Hart district in eastern San Bernardino County, California, are in hydrothermally altered Tertiary rhyolites (Kelly, 1966).

Most ball clay occurs in transported sedimentary deposits, but one minor producing district in California contains hydrothermally altered clay. The deposits in the Tennessee, Kentucky, and Mississippi districts are in sedimentary formations cropping out along the eastern edge of the Mississippi embayment. According to one theory of origin (Olive and Finch, 1969), they accumulated in an elongate broad

valley. The abundance of plant remains and organic matter associated with this clay indicates that the depositional basins probably were swampy.

Distribution of Deposits: United States—Any attempt to estimate the resources of ball clay is based on piecemeal information. The reserves, primarily in Tennessee and Kentucky, total probably as much as 100 million tons, and are owned by eight or ten different companies; they are thought adequate to sustain the industry for 100 years (Phelps, 1972). Additional reserves are in the producing districts in Mississippi, Texas, and California. Potential resources of low-grade ball clay, which probably would require beneficiation for market, occur in the vicinities of all of these districts. The prospects are also favorable for the discovery of more deposits of kaolinitic clay having the physical properties of ball clay in several southern states. Furthermore, if the term ball clay is applied to such deposits as the hydrothermally formed clay at Hart, CA, many areas in the western states are likely to contain large deposits.

Other Countries—The principal ball clay deposits in the United Kingdom occur in the Bovey Basin southeast of Dartmoor in Devonshire, the vicinity of Petrockstow in north Devonshire, and in the Wareham and Poole regions of Dorsetshire. These ball clays occur in sedimentary rocks of Tertiary age, consisting mainly of lenticular units of sand, clay, and lignite of probable lacustrine origin (Scott, 1929).

Ball clay occurs at several localities in India (Arogyaswamy, 1968), but production is limited, and in recent years India has been an importer of ball clay. The best quality ball clay produced is in the Than district of Gujarat. Other deposits are mined in two districts in Kerala.

Evaluation of Deposits: The prospecting techniques for ball clay are very similar to those outlined for kaolin. The most commonly used tests are very similar to those used for evaluating the ceramic properties of kaolin and heat-resistant properties of refractory clays. Chemical analysis for soluble sulfate in ball clays is commonly required because this material can be tolerated in only very minor amounts in most ceramic products.

Halloysite

History and Uses: Apparently the first halloysite used in the United States was that mined on a small scale near Rising Fawn, GA, in the late 1800s. This clay is reported to have been sold as a filler or extender in food (Veatch, 1909). Deposits near Gore, GA, were mined and used for making alum about 1912 (Broadhurst and Teague, 1954). A few hundred tons of halloysite was mined from deposits in Indiana and used for pottery and alum during and after World War I (Callaghan, 1948). The major source of halloysite in this country has been the approximately 1 million tons mined from the Dragon mine, Tintic district, Utah, by The Anaconda Co. It is processed into petroleum-cracking catalyst at the Filtrol Corp. plant in Salt Lake City, UT. Mining to supply this plant began in 1949. Minor tonnages of halloysite were produced from this same mine before 1949 for other uses. Halloysite occurring at several other places in Utah has also been used in making light-colored brick, firebrick, tile, and as a paper filler (Van Sant, 1964). Halloysite in Nevada has been used in portland cement in recent years (Papke, 1971). Deposits in Idaho consisting of mixed kaolinite and halloysite are used in refractories (Hosterman, et al., 1960), and deposits of similar clay-mineral composition in North Carolina (Parker, 1946) are mined for use in ceramics and other products.

Geology: Mineralogy—Halloysite is so similar to kaolinite that the two cannot be distinguished without careful mineralogical work (Brindley, et al., 1963). Very fine tubular structures commonly observable in electron micrographs of dehydrated halloysite (metahalloysite) are ordinarily diagnostic of this mineral. The shortcoming of this criterion is that not all metahalloysite occurs in the tubular form. A reliable criterion is that the basal (001) spacing of halloysite is at approximately 10Å; as halloysite converts irreversibly to metahalloysite, the spacing collapses to about 7.2Å, which is essentially the same spacing as for kaolinite. Halloysite, therefore, can be identified by the greater spacing in X-ray diffractograms of samples containing natural moisture.

Nonclay minerals and other impurities in halloysite vary considerably in different deposits. Some deposits, such as those in the Dragon mine, Utah, are exceptionally pure and contain only minor quantities of contaminants, consisting chiefly of pyrite, silica, dolomite, iron-bearing minerals and noncrystalline materials, and manganese oxides (Morris, 1968). In most deposits, silica is the principal impurity; it occurs in the form of quartz, cristobalite, chert, and poorly crystalline forms. Many halloysite deposits are intermixed with kaolinite, and several in western United States are closely associated with alunite. Gibbsite and manganese minerals also occur in some halloysite deposits.

Occurrence and Origin—Small deposits of halloysite occur at many places in the United States, but known deposits large enough to mine profitably are rare. The deposits in the Dragon mine, Utah, the major producer, are two large pipe-like bodies replacing lower Paleozoic limestone near the contact with monzonite porphyry (Kildale and Thomas, 1957). The two bodies are separated by a zone of iron-oxide deposits extending along the Dragon fissure (Morris, 1968). The occurrence of these deposits and the minerals associated with them clearly indicate that they formed by hydrothermal activity. Other deposits thought by Papke (1971) to have formed hydrothermally occur in the Terraced Hills, Washoe County, Nevada. These deposits are bedded and apparently altered mainly from tuff. The halloysite in the Gore district, Georgia, is bedded and occurs in the Armuchee Chert of Devonian age (Broadhurst and Teague, 1954). An adequate explanation of these deposits has never been advanced, but the extent of the beds suggests that they are of sedimentary origin. Halloysite mixed with kaolinite in the Spruce Pine district, North Carolina (Hunter and Hash, 1953; Parker, 1946), and the Bovill district, Idaho (Hosterman, et al., 1960), is mainly residual and formed by the weathering of igneous rocks. Several deposits in foreign countries are thought to have formed hydrothermally, and some are the result of surficial weathering.

Distribution of Deposits: United States—Virtually all major productive halloysite deposits in the United States have been referred to in the foregoing discussions. Most of the many other known scattered deposits are either too small or too impure to be considered as significant sources of halloysite. Possible exceptions include the following: (1) the halloysite mixed with kaolin in weathered nepheline syenite masses in the Arkansas bauxite region (Gordon, et al., 1958); (2) the body of halloysite reported to have been exposed for 107 m (350 ft) in the adit of a mine in the Bullion (Railroad) district, Nevada (Olson, 1964); and (3) rather extensive deposits reported near Bartow, GA (Anon., 1959). Possibilities for the discovery of new large high-grade deposits are not easy to evaluate. The likelihood of major discoveries does not seem promising, but rocks in many large areas in western United States have been altered hydrothermally, and several

of these could contain large deposits of halloysite. Also, resources of halloysite in the old Gore mining district in Georgia are estimated at more than a million tons (Broadhurst and Teague, 1954), and some use may again be found for these deposits.

Other Countries—Halloysite occurs in many countries, but, as in the United States, most deposits are small; the authors are aware of small-scale mining only in Morocco, Japan, Korea, Czechoslovakia, and New Zealand. The deposits mined in Morocco are in the Maaza district about 6 km west of Melilla (Hilali, et al., 1969; Martin Vivaldi and Vilchez, 1959).

Halloysite mined in Japan includes deposits that formed by hydrothermal alteration of granite and quartz porphyry and others that were transported and deposited in sedimentary basins (Takeshi and Kato, 1969). Hydrothermal deposits occur at the Taishu mine, and white sedimentary halloysite is in the Tajimi and Arikabe deposits.

The halloysite mined in Korea is presumably from the San Chong and Tan Song deposits described by Kim and Kim (1964).

The halloysite deposits mined in Czechoslovakia are in the Michalovce district in the eastern part of the country (Kuzvart, 1969).

The deposits in New Zealand occur in the Maungaperua district on the North Island. This clay is mined by New Zealand China Clays, Ltd., and sold for use in paper filler, ceramics, paint extenders, and filler for adhesives and cosmetics. The halloysite is in massive deposits formed by hydrothermal alteration of andesite of middle Cenozoic age (Bowen, 1969).

Several of the kaolin deposits in other countries consist of mixtures of halloysite and kaolinite. One such mixed deposit occurs in altered felsitic volcanic rocks in the Burela district, Spain (Anon., 1972b), the principal kaolin-producing center in that country. The kaolin produced contains appreciably more halloysite than kaolinite, but the clay must be considered to be a mixed type. Another mixed halloysite-kaolinite deposit is in the Bukidon district in the Philippines (Comsti, 1969).

Refractory Clays

History and Uses: The first plant in the United States for making refractory products from clays began operation at Salamander, NJ, in 1825. The refractory industry grew rapidly and expanded from New Jersey to centers in Pennsylvania, the Ohio River valley, Missouri, and to western states.

Refractory clays are used mainly in making firebrick and block of many shapes, insulating brick, saggars, refractory mortars and mixes, monolithic and castable materials, ramming and air gun mixes, and other products. A product called *chamottes* in Europe (Anon., 1972, 1972i) and elsewhere is made by calcining high-grade fire clays and other kaolinitic clays. A similar material produced in the United States is called merely calcined clay or calcined kaolin. A related material called mullite refractory is made by calcining bauxitic clay or clayey bauxite. Further fabrication into finished refractory products is required for chamottes and calcined clay. Considerable tonnages of fire clay also have been used in the past in the United States in the manufacture of light-colored face brick, tile, stoneware, and other products.

Geology: The mineralogy, occurrence, and origin of refractory kaolin and refractory ball clay have been discussed in the foregoing sections. Therefore, the following discussions

will be concerned with these subjects only as they apply to fire clay.

Mineralogy—The degree of ordering of the kaolinite, the principal mineral in fire clay, varies considerably. Most of the kaolinite in the harder and purer varieties of fire clay (flint clay) is very well ordered, and it is even more perfectly crystalline than the kaolinite in many kaolins. The kaolinite in the hard fire clay also tends to occur in coarser particles, and in the harder varieties the grains are interlocking. The kaolinite in the plastic varieties of fire clay, however, is ordinarily characterized by imperfectly crystalline structures. The more disordered form of this kaolinite has been widely referred to as fire clay mineral in an effort to distinguish it from the more perfectly crystalized forms.

Some of the better grades of refractory clays contain minerals that are richer in aluminum than kaolinite, and, therefore, higher alumina products can be made from them. Some refractory kaolin is a mixture of kaolinite and gibbsite, $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$. The better grades of fire clay, that are exceptionally rich in aluminum, consist of kaolinite and diaspore, $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$, and minor quantities of boehmite, $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$.

Occurrence and Origin—The physical characteristics of fire clay vary considerably; the clays range from soft and plastic to flintlike. Fire clay, therefore, is divisible into plastic, semiplastic, semiflint, and flint types. Flint clay has unique properties for a clay; it lacks plasticity, breaks with a conchoidal parting into shardlike particles, and most of it is as hard as limestone. Typical diaspore-bearing flint clay is hard and has an oolitic, pisolitic, or nodular texture. Such clay is referred to as burley, birdseye, or nodular clay.

Most fire clay occurs in sedimentary rocks, and deposits range in age from Pennsylvanian to Tertiary. Fire clay is particularly common in rocks of Pennsylvanian age, and deposits of this age occur as underclays (seat earths) immediately below or closely associated with coalbeds. Fire clay of Cretaceous and Tertiary age occurs mainly in lenticular bodies. Some deposits of these ages are associated with lignite and are probably underclays, and others have apparently been transported and deposited in local basins in a nearshore, swamp, or flood-plain environment.

Opinions differ considerably on the origin of the extensive fire clays occurring below coalbeds. Some geologists (Keller, 1970; Patterson and Hosterman, 1963), including the authors, believe that most underclay deposits formed mainly by the alteration of aluminous sediments in a swampy environment. Some mineralogists, however, believe that these clays were transported and some sort of a sedimentary winnowing process caused the rather pure accumulations of kaolinite in fire clay. Some clays of Cretaceous and Tertiary age have been transported and formed by a process similar to those thought to have formed the transported kaolin deposits.

Distribution of Deposits: United States—Fire clay of Pennsylvanian age is widely scattered throughout the Appalachian region and parts of the Mississippi Valley (Anon., 1967). The very high quality diaspore-bearing clay, as well as other grades of fire clay, occur in the Clearfield district, Pennsylvania (Anon., 1964; Bolger and Weitz, 1952), and the Ozark region in Missouri (Keller, 1952; Keller, et al., 1954). High grade kaolinitic flint clay and semiflint clays are mined in the Olive Hill district, Kentucky (Patterson and Hosterman, 1963); Oak Hill district, Ohio (Stout, et al., 1923); and Somerset district, Pennsylvania (Hosterman, et al., 1968). Major districts producing fire clay suitable for low- and moderate-heat-duty refractory products include the Allegheny Valley and Beaver Valley districts, Pennsylvania;

Cordova district, Alabama; East Liverpool district, Ohio and West Virginia; and the Tuscarawas Valley and Hocking Valley districts, Ohio (Hosterman, et al., 1968); and a region including parts of Monroe, Audrain, Callaway, and Montgomery Counties, Missouri (McQueen, 1943).

The largest and best quality fire clay deposits in the Rocky Mountain region are in Fremont, Pueblo, Custer, Huerfano, Jefferson, and Las Animas Counties, Colorado. These deposits are in the Purgatoire Formation and Dakota Sandstone of Cretaceous age (Waagé, 1953). In addition to the fire clay mentioned in the foregoing discussions, other deposits are scattered throughout the western states (Anon., 1967; Mark, 1963; Van Sant, 1959, 1964). Districts in which these scattered deposits occur include several areas in King County and the Castle Rock area in Cowlitz County, Washington; the Molalla and Hobart Butte areas, Oregon; and the Alberhill area, California. Most of these deposits are of Cenozoic age.

Refractory kaolin is produced primarily in the following districts: (1) Georgia-South Carolina kaolin belt; (2) Andersonville, Georgia (Anon., 1972a); (3) Eufaula, Alabama; (4) Arkansas bauxite region; (5) scattered districts in Texas; (6) Latah County, Idaho; and (7) Ione, California (Anon., 1972e). Refractory ball clay is produced primarily in the western parts of Kentucky and Tennessee, but some of the ball clay produced in Texas may be used in refractory products.

Other Countries—Refractory clays are produced in many countries; however, the information available to the authors on worldwide production is sketchy and incomplete. This is partly because the distinction between fire clay and miscellaneous clay is not made in some countries, and clay used for refractory products is lumped with kaolin in others.

Those countries that produce more than 1 million tons of refractory (fire) clay annually include the United Kingdom, Federal Republic of Germany (West Germany), and Japan. The production in France exceeded a million tons a few years ago but has apparently dropped below this figure in recent years. Other countries producing 100,000 to 1 million tons annually include Argentina, Australia, India, Italy, Mexico, New Zealand, Sweden, the United Arab Republic, Uruguay, and Yugoslavia. Refractory clay is exported from the Peoples Republic of China, which is apparently a major producer. Fire clay is also mined in the USSR, Czechoslovakia, Hungary, Poland, and other East European countries.

Exploration and Evaluation: The methods used in exploring and evaluating fire clay deposits are in general similar to those used for bentonite and kaolin, except that different drilling and testing procedures are required. Drilling fire clay deposits, particularly those of Pennsylvanian age, ordinarily requires diamond bits and core barrels of the type used for minerals in hard rock. This is because the clay itself and the rocks overlying the deposits are hard. The most common test in the evaluation of fire clay is the determination of PCE (pyrometric cone equivalents).

In addition to the PCE requirement, fired test pieces also may be tested for such properties as high-temperature stability, hot strength, porosity, and spalling (Anon., 1972h; Norton, 1968). Chemical analyses are also required for some evaluations, and the contents of alkalies, alkaline earths, iron oxides, and a few less common elements are critical, because they act as fluxes when clay refractories are heated.

MISCELLANEOUS CLAY AND SHALE

Miscellaneous clay and shale includes a wide variety of clay and other fine-grained rocks that are used in many ways.

Most products made from them are fired and include such things as structural and face brick, drain tile, vitrified pipe, quarry tile, flue tile, conduit, pottery, stoneware, and roofing tile. Very large tonnages of these materials are bloated by firing to form lightweight aggregate, and large quantities are used in making portland cement. Uses not requiring firing of a finished product include filler for paint and other products and shale and clay used for packing dynamite in blast-holes and for plugging oil and gas wells that are no longer in use. Adobe building blocks are also used in unfired form in several southwestern states.

Properties

Clay and shale are used in so many different structural clay products that they necessarily have a wide range in physical properties. The properties are plasticity, green strength, dry strength, drying and firing shrinkage, vitrification range, and fired color. The properties desired vary with the structural clay product made. For example, a clay used in making conduit tile must be very plastic and have high green and dry strengths and uniform shrinkage, but for drain tile or common brick these properties do not have to be controlled so closely.

Occurrence

Miscellaneous clay and shale occur in many types of rocks ranging in age from Precambrian to Holocene. They include glacial clay, soils, alluvium, loess, shale, weathered and fresh schist, slate, and argillite. Some fire clay and kaolin are also included in the miscellaneous clay group, particularly when used in the manufacture of structural-clay products. This group consists of so many different types of rocks that only a few broad generalizations about their mineral makeup are possible. The most common mineral in many of them is one of the members of the mica group, and the dominant one in a given deposit may be illite, sericite, or one of the micas normally occurring in coarser grain sizes, such as muscovite and biotite. In addition to illite, the clay minerals present commonly are kaolinite, smectite, mixed-layer varieties, and chlorite. Some materials in this group actually contain more quartz and other detrital minerals than clay minerals.

Miscellaneous clay and shale are now mined in every state in the United States, except Alaska and Rhode Island, according to US Bureau of Mines *Minerals Yearbooks*. The states producing more than 1 million tons are Alabama, California, Georgia, Illinois, Indiana, Iowa, Louisiana, Maryland, Michigan, Missouri, New York, North Carolina, Ohio, Pennsylvania, South Carolina, Texas, and Virginia.

6. Diatomite

FREDERIC L. KADEY, JR.

Diatomite is a siliceous, sedimentary rock consisting principally of the fossilized skeletal remains of the diatom, a unicellular aquatic plant related to the algae. Thus, it has been formed by the induration of diatomaceous ooze and consists mainly of diatomaceous silica, a form or variety of opal which is first formed in the cell walls of the living diatom. Diatomaceous silica is not generally regarded as a synonym or the equivalent for diatomite, although it has been so used at various times. Accurately, diatomaceous silica is the preferred name for the principal mineral component of which the rock, diatomite, is composed. The terms diatomaceous earth and kieselguhr are used as synonymous with diatomite. The designations tripoli, tripolite, infusorial earth, etc., were used at one time but are now obsolete. With the changing nomenclature, these terms that were at one time correct when proposed and used for generations would be considered incorrect if used today in the light of current knowledge. The designation diatomite is reserved for those accumulations of diatomaceous silica that are of sufficient quality, size, and minability to be considered of potential commercial value.

GEOLOGY

Composition and Morphology

Diatomaceous silica qualifies as a mineral of organic origin in much the same way that aragonite and collophane do. The silica of the fossilized diatom skeleton closely resembles opal or hydrous silica in composition ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$) (Cummins, 1960; Lohmann, 1960).

The silica is of acute biological significance, not only for the cell wall component, but also for the basic life process. Without silica, cell development ceases (Arehart, 1972).

In addition to bound water, varying between 3.5 and 8%, the siliceous skeleton may also contain, in solid solution or as part of the SiO_2 complex, small amounts of associated inorganic components—alumina, principally—and lesser amounts of iron, alkaline earths, alkali metals, and other minor constituents. Boron is reported to be an essential element for diatom growth (Lewin, 1966; Neals, 1967).

Since diatomaceous silica is not pure hydrous silica but contains other intimately associated elements, there is good reason to consider it a distinct type or variety. Associated with the diatomaceous silica, and integrated as part of the diatomite, may be variable amounts of organic matter, soluble salts, and particles of rock-forming minerals that were syn-genetically deposited or precipitated with the diatom frustules. Sand, clay, carbonate, and volcanic ash are typical common contaminants. Other contaminating minerals may be present, such as feldspar, mica, amphiboles, pyroxenes, rutile, zircon—the result of weathering, then transporting, and subsequent redeposition of surrounding land masses. Commercial diatomite may also contain fragments and particles of other such organisms as silico-flagellates, radiolaria and siliceous sponges.

In a commercial diatomite, silica makes up the bulk of the chemical composition, usually over 86% and as high as 94%. Alumina and iron generally are at least 1.5 and 0.2%, respectively. This includes not only that believed to be incorporated as part of the skeleton but iron and alumina associated with many of the contaminants. Lesser amounts

of other elements, a small part of which may be secreted in the diatom skeleton, comprise the balance of the total chemical composition. The manner in which many of these elements are associated is not presently known. Table 1 illustrates the chemical composition of diatomites from various areas (Cummins, 1960).

Processed diatomite possesses an unusual particulate structure and chemical stability that lends itself to applications not filled by any other form of silica. Foremost among these applications is its use as a filter aid, which accounts for over half of its current consumption. Its unique diatom structure, low bulk density, high absorptive capacity, high surface area, and relatively low abrasion are attributes responsible for its utility as a functional filler and as an extender in paint, paper, rubber, and in plastics; and as an anti-caking agent; thermal insulating material; catalyst carrier; and chromatographic support; polish, abrasive, and pesticide extender to name a few representative applications.

The United States is the principal producing country, although diatomite is found in numerous other locations.

MINING METHODS

In the United States, diatomite is only extracted from quarries and open pits. Generally, a waste to ore (overburden) stripping ratio of up to 4:1 is ideal, although stripping ratios of up to about 7:1 have been economically feasible under particular conditions. Elsewhere in the world, although open pit mining is obviously preferable, underground mining methods have also been used successfully, where the stripping ratio would otherwise be economically prohibitive or the crude is overlain by dense material such as a basaltic cap.

In Iceland, commercial diatomite, deposited on the bottom of Lake Myvatn is dredged from beneath about 1 m of water and pumped in slurry to the processing plant 2 km away.

Diatomite of commercial significance in northern Brazil is being chopped into blocks by hand from shallow bogs and stacked in piles for field drying.

MODE OF OCCURRENCE AND ORIGIN

The frustule or siliceous skeleton of the diatom, a unicellular or noncellular microscopic algae, of the class Bacillariophyceae, and the order Bacillariales, serves as the ultimate building block of which diatomite is composed. The group comprises over 300 genera and 12,000 to 16,000 species. In living form, accumulations of the diatom may be seen as the iridescent scum on ponds, the slippery gelatinous film on seaweed, on the bellies of certain species of whales, and other such varied habitats as oceanic ice floes, hot springs, moist soil, and particularly as masses of planktonic colonies on the open sea. Their natural function appears to be that of a food for other organisms of the sea. Furthermore, their role in controlling the geochemical balance of silica in marine and in lacustrine waters is scientifically recognized (Calvert, 1968; Kilham, 1971).

Environmental conditions for growth include at least the five following major requirements:

- 1) Large shallow basins (preferably 35 m or less in depth) for deposition, so that photosynthesis can occur. With regard to lacustrine deposits, a shallow lake provides suffi-

cient actinic light for photosynthesis for not only pelagic diatoms, but also for benthonic forms attached to stones and to plants on the lake bottom. In the case of thick deposits of marine diatomites, there is evidence for a down warping of the basin of deposition, thus maintaining fairly shallow water for benthonic species. The open sea is reportedly the best environment for pelagic diatoms.

2) An abundant supply of soluble silica (Kilham, 1971; Lewin, 1959).

There is a worldwide correlation between the existence of thick diatomite deposits and proximity to volcanic ash occurrences. While volcanic ash does not necessarily have to accompany diatom deposition, some mechanism for increasing the silica content in marine and lacustrine bodies beyond the present day norm is necessary for the formation of commercially thick deposits. There are numerous examples wherein marine and nonmarine deposits meet this condition. Typical of these are at Lake Myvatn, Iceland; in the state of Jalisco, Mexico, where the deposits border the ancient shores of Lake Atotlanilco; and those occurrences bordering Lake Rotorua, New Zealand; in Nevada the late Miocene Virgin Valley beds in Humboldt County, and the early Pliocene Esmeralda formation in Nye and Esmeralda Counties; the Payette formation in Idaho and eastern Oregon. These all are associated with volcanism. Deposits of marine diatomite exhibit a similar correlation; the late Miocene-early Pliocene Sisquoc formation which comprises the Lompoc, CA, diatomite; the middle and late Miocene Monterey formation of the Coast Ranges; and the middle Miocene Tremblor formation east of Coalinga, CA, are examples of diatomites associated with contemporary volcanism. Particles of volcanic ash are a common contaminant of some diatomites.

3) An abundant supply of nutrients. In most lakes that are nontoxic to diatom proliferation the supply of nutrients is often more available than is the supply of silica.

4) The absence of toxic or growth-inhibiting constituents in the water. Although few lakes contain toxic water in the usual sense, many in which the rate of evaporation exceeds inflow during long periods of the year build up concentrations of soluble salts to the point of inhibiting diatom growth (Jorgensen, 1969; Chin, et al., 1965).

5) A minimum supply of clastic sedimentary materials. While this, per se, is not a requirement for diatom growth, low nondiatomaceous contamination is paramount for the development of a commercially suitable deposit.

The effect of temperature, light, pressure, and other factors on diatom growth has been discussed (Berger, 1971; Felfoldy, 1961; Patrick, 1971). In addition to its unique siliceous skeleton, the living form has a nucleus, it produces certain protoplasmic substances by the process of photosynthesis, and, incidental to its metabolism, it manufactures oil and vitamins. The rate of reproduction of diatoms varies with the species from between two or three times a day to once a week; and one diatom may have 100 million descendants in 30 days. Deposition of the skeletal remains occurs after it has served its natural function. Thus, given the right conditions of environment and geologic location, tremendously thick deposits of diatomaceous ooze may build up on the floor of the containing body of water.

Potassium-argon dating of volcanic minerals and glass in North Pacific sediments has established Tertiary sedimentation rates of from less than 1 mm per 1000 years for deep sea red clay, to 1 cm per 1000 years for calcareous-siliceous ooze nearer the continent. In comparison, the rhythmic banding seen in Lompoc, CA, diatomites suggests a rate considerably faster than that—probably of the order of 1 mm or more per year. Gross has calculated a sedimentation rate of 4 mm per year for a 25% diatom-75% silt sediment, deposited in Sannich Inlet, BC. (Gross, et al., 1963)

After deposition, such subsequent geologic forces as consolidation, burial under what will later be overburden, regional uplift, and partial erosion come into play to expose, yet protect, the deposit for later discovery and exploitation.

Because of the delicate nature of the diatom skeleton, deposits of diatomite to be useful to industry cannot undergo any great degree of regional metamorphism or chemical alteration. For this reason, geologic conditions that have not resulted in an appreciable degree of consolidation or of cementation are preferable. When orogenic forces are excessive, the resulting metamorphosis produces opaline cherts, porcelanites, and similar more indurated materials of noncommercial interest.

In place, diatomite is soft and "punky" and has a chalk-like appearance. Color may vary from snow white in a pure, well bleached and dry deposit, to olive green or darker where substantial organic remains are still present and where moisture content is high. It may exhibit stratification, caused by either, or both, sedimentation of particularly flat beds or a preponderance of discoid diatoms, or by seasonally rhythmic deposition of clay and other impurities. On the other hand, it may be massive and show no stratification. It may be so

loosely consolidated that, when handled, a field sample will readily break down to a powder, or it may be hard enough to crack "brittley" when struck with a hammer. In addition to induration through consolidation, precipitation of carbonate for example, or "baking" by volcanic flows can destroy an otherwise good deposit. The better quality diatomite is lightweight, usually possessing a block density between 320 to 545 kg/m³ (20 to 34 pcf).

CLASSIFICATION OF DEPOSITS

The various species of diatom thrive in either a marine or a lacustrine environment. Some forms live in brackish waters. Identification of the diatoms from an unknown deposit label it as having been laid down in either one environment or the other. It is, therefore, to be expected that a major criterion of deposit classification deals with whether it is of marine or of freshwater origin. Some investigators have added to the environments just mentioned, whether deposits are of modern lake, marsh, or bog origin (Durham, 1973).

These criteria are important because the diatom assemblages associated with marine environments are quite different from those that live only in freshwater habitats. The association of forms or the diatom assemblage, as seen by means of the microscope, not only serves to differentiate marine origin from freshwater, but also in many cases, to identify the deposit location from which an unknown sample may have come. Diatom assemblages, like fingerprints, are specific to individual locations. Because of the structural differences related to origin, as has been pointed out, diatomites have a range of properties and produce a range of effects in the numerous uses to which they have been applied. Numerically, most of the known deposits in the world are of lacustrine origin. Generally however, those of marine origin, although less numerous, tend to be larger.

DISTRIBUTION OF DEPOSITS

The occurrence of diatomaceous silica is widespread throughout the world. Although algae appeared quite early in geologic history, commercial deposits are generally restricted to sedimentary formations of Tertiary and of later age, and further limited ecologically by those conditions for formation that have been previously described. However, when one considers the numerous other limiting factors that must be taken into account before an occurrence qualifies as a commercial deposit—quality, minability, location, and size—then the numbers are few indeed.

North America

United States: Occurrences of diatomite have been reported from just about all of the east and the west coastal states, and indeed, from many bordering these states in the interior of the country. Commercial production, however, has been limited to a few of these. First American production was from Maryland, where from 1884 until 1930, marine diatomite was extracted from the Fairhaven member of the middle Miocene Calvert formation. This diatomite outcrops along the banks of the Patuxent, Rappahannock, and Potomac rivers, and in cliffs along Chesapeake Bay. It is contaminated with varying amounts of loosely held silica sand, most of which can be removed in processing. More intimately held montmorillonite, illite, and kaolinite are also present. Removal of the clay on an experimental basis has been attempted with little practical success, for other than low quality applications (Knechtel, and Hosterman, 1965).

The largest and most uniform deposits in the world are to be found in the vicinity of Lompoc, CA. The diatomite

sequence of commercial significance is of the order of 305 m (1000 ft) thick and is part of a thicker diatomite series of marine origin belonging to the Sisquoc formation of late Miocene or possibly early Pliocene age. Although the Lompoc diatomite may have been known since the time of the Spanish Conquistadors in the 1760s, it was not recognized as such until over a century later, and first mining was not started until about 1890. The strata at Lompoc, which present a good example of rhythmic bedding, are mined principally from a broad pitching syncline with related smaller anticlines and synclines.

Diatomite was mined from a deposit in the Palos Verdes Hills near Los Angeles starting in the 1930s, but that deposit is now depleted (Rowell, 1980). A massive embayment or commercial freshwater diatomite in Shasta County has been outlined recently. There are other minor operations in California (Clark, 1978).

Second to California in production is Nevada, where diatomite from freshwater deposits is mined in two principal areas from deposits near Lovelock and at Clark, near Reno. These are of late Tertiary or Pleistocene age. The beds at Clark are close to the surface and are relatively low in moisture.

Diatomite is also mined from a freshwater deposit near Basalt, about 97 km (60 miles) from Tonopah in southwestern Nevada. In the state of Washington, diatomite is produced from a lacustrine deposit near Quincy. At one time, there was production from a deposit at Kittitas, WA. Minor production has been reported from Oregon and from Arizona. Other states that have produced diatomite in the past include Idaho and Utah. A mixture of carbonate and freshwater diatomite in western Kansas was mined until 1977. Florida has bog and lake bottom deposits near Pensacola and in central Florida that have received exploratory attention in the past. Noncommercial bog and lake deposits are well known in Maine, New Hampshire, Massachusetts, and New York. Some of these were operated on a small scale in earlier years.

Canada: Production in Canada at present is limited to freshwater Miocene deposits near Quesnel, BC. Eastern Canada has well-known occurrences in Nova Scotia and New Brunswick that are not profitable to exploit at the present time.

Mexico: Diatomite occurs in several states in Mexico, and among these are Tlaxcala, Colima, Jalisco, Michoacan, and Mexico. Some production has been known since 1927. Good quality earth is mined near Catarina in Jalisco. Other commercial deposits are exploited at Zacapu and at Tuxpan by Kieselguhr de Mexico in Michoacan. Production has been reported at Magdalena and Cocula in Jalisco, at La Blanca in Tlaxcala, at San Martin Texmelucan in Puebla, and at Ixtlahuaca in the state of Mexico.

Europe

The most significant European sources of diatomite are freshwater Tertiary and Quaternary deposits located in the Massif Central area of southern France.

The Luneburger-Heide deposits of Western Germany were the first commercially mined deposits in the world, but have declined in importance in recent years. In Italy, commercial deposits are located at Arcidosso and Santa Flora and further south in the Viterbo area and at Castiglione in Teverina. Medium grade diatomite is mined in the area of Tombolia in northern Italy. Good quality Spanish diatomite is mined from lacustrine deposits between Hellin and Elche de la Sierra in the southeastern part of the country. Some

of these deposits were mined from underground galleries for over 50 years, but in recent years have been converted to open pit operations. Some of the earth is a remarkably white color, but chert lenses and carbonate beds necessitate highly selective mining methods. There are other, low quality occurrences in Spain, including a marine occurrence near Almeria. In Iceland, a diatomaceous ooze of Holocene Age is dredged from Lake Myvatn and pumped in slurry to the processing plant where the volcanic ash is removed by hydroclones.

The diatomite of Skye, Scotland, has been known for some time. Some diatomite is mined from a wet lake basin deposit near Kendal in Westmoreland, UK. The earth is dark in color and is not suitable for filter aid manufacture. It is used mostly for thermal insulation.

An unusual, but commercially viable deposit, is the diatomite-clay mixture of Denmark called Moler. This earth is not suitable for filter aids because of the iron oxide and clay content, but it is exported elsewhere in Europe for fertilizer coating and for insulating. Moler is of marine origin and of Tertiary age and occurs on the islands of Fur and Mors in northern Jutland. Some diatomite of good quality has been produced in recent years in southern Denmark.

There are numerous deposits in the USSR, although little information is available. Freshwater diatomite deposits exist near Prilep, Yugoslavia, and in central Anatolia, Turkey. Romania has a lacustrine deposit near Adamclisi. Small unproductive deposits occur in many other European countries.

Africa

Impure diatomite, suitable only for insulating materials, is mined from a deposit in the Ermelco District, Transvaal, and from a deposit in the Prieska District, near Postmasburg, Cape Province.

East Africa produces both filter aid and filler grade products from deposits near Gilgil, Kenya. These were deposited in Pleistocene lakes in the Rift Valley. Several other smaller deposits are not of current economic interest.

Marine deposits of Miocene age occur near Sig (formerly St. Denis-du-Sig) in Algeria. These are mined from underground galleries. There is a marked similarity in appearance between the Algerian and Lompoc diatomites when viewed under the microscope. The diatomite from Algeria, however, is characterized by a noticeable amount of carbonate contamination and is deficient in many of the diatom types that, in the Lompoc earth, provide a better balance for filtration. Numerous, intensely folded, thin beds occur near Mostaganum, Algeria.

South America

Diatomite is mined from small, scattered deposits in Rio Negro Province in Argentina. Much of the earth occurs under a basalt cap, which necessitates mining from galleries and in one instance as an open pit operation after blasting away the basalt. There are also small impure occurrences in San Juan province near Calingasta, and in remote parts of Salta Province. There are numerous bog deposits in Brazil. The states of Ceará and Bahía contain the most deposits, although eight other states are reported to have smaller impure occurrences. Peru has occurrences at Pisco, Piurá, Chiclayo, and Arequipa; and Chile has deposits of high brightness earth at Arica and Chiloe. In Colombia, diatomite occurs at Tunja and Antioquia. Diatomite occurs to a lesser degree in other Latin American countries.

Asia

There is considerable potential for development of deposits in the Far East. Japan has a growing industry based

on its own marine and lacustrine deposits. Deposits, possibly suitable for local markets, exist in Indonesia and in Korea.

Diatomite deposits within China are widespread but localized and small. These are used mainly for production of construction and insulating materials.

There are several small deposits in Australia and in New Zealand, but for filter aid quality, these countries depend on imports, principally from the US. The pressure from increasing transportation costs, however, is lending motivation to the exploration and possible development of shallow mediocre quality bog deposits in Western Australia near Perth and Geraldton.

Elsewhere in the world are numerous other occurrences of diatomaceous silica which, for one reason or another, have not been exploited. Furthermore, accumulations of diatomaceous ooze are forming today that will constitute the deposits of "tomorrow."

EXPLORATION

Keeping in mind the previously described limiting criteria for formation, prospecting for diatomite entails reconnaissance of potentially suitable terrain. Because it is usually soft and easily eroded, white "showings" in stream banks or in road cuts should be investigated.

Since virtually all of the surface exposures of diatomite—at least in the United States—have been recognized, if not sampled, explorationists have shown increasing interest in geophysical methods as an opportunity to uncover as yet unknown diatomaceous sediments. Geophysical methods are increasingly contributing to the search for industrial minerals in general (Crice, 1980). Geophysical refraction seismic surveys have successfully outlined the depth of shallow freshwater diatomite basins. This works particularly well where the soft (low velocity) diatomite is underlain by higher velocity basalt (C.M. Smith, Grefco, Inc., personal communication). In addition to seismic methods, Manville Corp. has also used resistivity methods in diatomite exploration (Breese, Manville Corp., personal communication). Narrow pass-band infrared imagery (3-4 and 4.5-5.5 micrometers) has been used to recognize diatomite from aircraft by its thermal characteristics (Carter, 1971). Changes in vegetation have been noted over diatomite-bearing areas of bog deposits, and this might indicate the possible application of geobotanical techniques in prospecting.

When carried to the point of development, exploration of diatomite deposits is pursued in stages. After an occurrence has been recognized through prospecting, usually, the first step in exploration consists of a preliminary sampling of all visible outcrops. The nature of the material is noted and recorded by measuring the attitude of the beds and by observing all other visible structural and stratigraphic features. Sampling intervals are divided into visible increments if bedding, textural, and color changes or stratification are evident. If thick enough and no visible divisions are apparent, the stratigraphic interval spanned by each sample should be no more than 150 cm for each channel cut. In this way, non-visible characteristics—diatom assemblage, chemical changes, etc.—may be noticed and characterized during testing of the samples. In subsequent exploration stages, the 150-cm interval may be reduced, if required.

The advantage of two- and three-stage exploratory programs is that exploration can begin with a relatively economically wide spacing of sampling locations. Upon testing of the samples from such a stage, a judgment can be made whether, because of unfavorable findings, the program should be aborted or if a subsequent program is needed in which the hole spacing is reduced.

Some preliminary field testing can be incorporated into the exploratory phase of deposit evaluation. Evidence of staining, degree of consolidation, judgment of color, bedding, and stratification, etc., are all field characteristics that are important, and which should be noted. Other obvious field aids include an HCl test for carbonate, a grit test by grinding the crude between teeth, and the noting of appreciable water solubles by taste.

The most useful tool in the field is a portable microscope. When performed by an experienced operator, microscopic examination in the field can be used to ascertain diatom constitution and contaminants, to direct the course of exploration, to provide a stratigraphic correlation, and to eliminate the shipping of useless samples to the testing center.

Pending favorable results from the laboratory evaluation of the samples, the next stage of exploration is planned to delineate the reserves within the area and to further assess the quality. With horizontal beds under relatively thin overburden and in areas of gently rolling topography, the digging or augering of vertical exploratory shafts to expose the entire stratigraphic column has proven highly satisfactory. In countries with low labor rates and in locations where mechanical equipment is difficult to maintain, hand-dug shafts up to 50 m in depth have many advantages. When these are of the order of 1 to 1½ m in diam, ingenious "bird cage" types of sampling platforms, lowered by windlass into the hole from a tripod arrangement, have been used to support a geologist, who logs the hole and collects samples from the wall of the shaft. Whether hand-dug or machine-bored with a large auger, these openings in the deposit have the advantage that the structure and nature of the beds may be noted and correlated from hole to hole. Where overburden is minimal or nonexistent, holes dug by backhoe have been used. While these have the advantage of the speed of excavation that is provided by mechanical equipment, depth is limited to about 6 or 7 m at the most.

It should be emphasized at this point that an essential element in diatomite processing, hence also in diatomite sample preparation, is that the delicate diatom structures—as they exist in the deposit—be disturbed or broken down as little as possible. This diatom structure must therefore be carefully preserved to the extent possible during sampling as well. The previously described "nondrilling" sampling methods are most satisfactory from many viewpoints, not the least of which is structure preservation. Where drilling cannot be avoided, however, it is recommended, at the outset, that rotary drilling which pulverizes the cuttings to the extent that a powdered sample is flushed up the hole by reverse air circulation not be used. While this method of sample retrieval may not be as undesirable for more highly consolidated materials that are suitable for aggregate applications, it is virtually useless for filter aid and functional filler applications where the amount of whole diatom structure needs to be preserved for evaluation. Furthermore, the loss of dust plus the minimum critical size of particle that is flushed for a given vertical sampling interval renders representative sampling most unreliable (Krech, 1973).

The recommended sampling method is by core drilling. Core drilling in diatomite is specialized and requires special equipment and experienced drilling crews. Triple barrel, wire-line diamond core equipment is highly satisfactory for loosely consolidated material. The more loosely consolidated the diatomite is, however, the more difficult it is to obtain high percent recovery with as little as a 4- or 5-cm diam core. A 5-cm diam core of 150-cm vertical interval will not produce sufficient material in a low density crude for more than a few of the evaluatory tests that are required. Therefore,

careful and judicious compositing of suites of similar samples may be required.

Where any amount of topographic relief is present, trenching by bulldozer on hillsides will expose the bedding and will permit subsequent channel sampling. The opening of trenches by bulldozer across the bedding of dipping strata will remove overburden and expose the strata for sampling.

The positioning of drill holes, shafts, or trenches to adequately cover a deposit depends upon a number of factors. Sample positions are most commonly arranged systematically in a grid to cover the area to be explored. The distance between sample locations is dependent, among other things, on the lateral variation in important properties or characteristics of the diatomite. Where important properties are thought or known to change rapidly with lateral extent, holes must be placed more closely together than when a high degree of uniformity is experienced in preliminary study. (Sample holes, on as close as 30-m centers, have been used.)

Subsequent stages of exploration consist of additional specialized sampling and of the selection of bulk samples for plant scale trials. Whereas the foregoing methods are suitable for dry deposits, specialized techniques must be developed for bog deposits and for those occurring under lakes or ponds.

In the case of shallow lakes, sample locations are marked with survey poles driven into the ooze. Peat bog samplers that extract a 30- to 60-cm incremental sample have been designed with long shafts so that a sample can be extracted from as much as 8 m below the surface. These may be used from a boat or raft that is floated into position and anchored.

While much useful information can be collected in the field, and can lead at that point to a firm recommendation by the geologist to *not* consider the deposit further, the ultimate judgment of quality, however, is formed from the results of usually extensive testing in the laboratory.

For the interested reader, the Diatomite chapter in the 5th edition of *Industrial Minerals and Rocks* contains a comprehensive treatment of this commodity (Kadey, 1983).

7. Feldspar*

Feldspars, the most abundant minerals of the igneous rocks, occur in numerous forms and mixtures. The feldspars of commercial significance are found in widely distributed pegmatites as large crystals usually free of iron-bearing impurities and thus suitable for hand-cobbing, and also in larger bodies where the ore contains various types of feldspar intermingled with quartz and relatively free of iron-bearing impurities, or at least readily unlocked from impurities present at relatively coarse mesh. The latter type of ore includes some pegmatites, and the "alaskite" bodies so common in the Spruce Pine district of North Carolina. On the west coast of the US and in Oklahoma there is—or has been—commercial recovery of natural feldspathic sand as a source of alumina in glass and ceramics. "Aplite" in commercial terminology is a light-colored igneous rock with a granitic composition and a fine sugary texture, often banded with readily removable iron impurities. Only one area in Virginia produces apfite for the glass industry; it is located near Montpelier in Hanover County.

According to Deer et al. (1966) the word feldspar derives from the Swedish *feldt* or *fält* (field) and "spath:" chunks of rock appearing in tilled ground overlying granite. Castle and Gillson (1960) indicate a Germanic origin, citing "spat," which is said to refer to any transparent or translucent material which is readily cleavable. The term "spar" has in the past been applied to minerals other than feldspar, such as barite, calcite, and fluorite. It is correct to call the latter "fluorspar." There is a true barium feldspar, but it is rare and of no present economic importance. What is recognized as feldspar or "spar" by present producers and consumers consists of three silicate minerals which, if pure, would have the formulas KAlSi_3O_8 (microcline or orthoclase), $\text{NaAlSi}_3\text{O}_8$ (albite), and $\text{CaAl}_2\text{Si}_2\text{O}_8$ (anorthite). These are almost never found in pure form in nature, but occur together in great abundance in a three-component system. A considerable number of different combined ratios of these three exists, with the exception that isomorphism between potassium spar and calcium spar is very limited. User specifications for feldspar products are largely built around the prevalent naturally occurring ratios. Passages following will refer to "K-spar," "Na-spar," or "Ca-spar."

NOMENCLATURE AND DESCRIPTIVE TERMS

Relating to both the mineralogy and the economics of feldspar are certain terms whose coverage it is useful to specify.

Commercially, *apfite* is a feldspathic rock mined and beneficiated in one location in Virginia, in which both titanium and feldspar minerals are present—the latter now being the major, if not the only, economic product. Technically, the term apfite when applied to this rock is of questionable accuracy. But, in light of accepted commercial usage, the term will be here used to designate it. Regarding the Virginia rock, Ross (1941) is cited.

Alaskite is another term requiring understanding if not precise use. A distinctive rock type customarily called by this name is found near Spruce Pine, Mitchell County, North

Carolina. An important major feldspar source, it contains somewhat higher levels of plagioclase feldspar and quartz than alaskite as defined in the *Glossary of Geology and Related Sciences*, which stated that "orthoclase, microcline, and subordinate quartz are the principal minerals" and "plagioclase may or may not be present." Brown (1962) notes a granitoid rock near Peakville in Bedford County, Virginia (a past commercial feldspar source) as being alaskite, but he also classifies the Spruce Pine rock as such. There is some professional disagreement as to whether the Spruce Pine rock is a granite or a pegmatite. In any event, the term "alaskite" will, in this chapter, pertain to the relatively coarse-grained granitelike Spruce Pine ore which is well known to the feldspar industry.

Graphic granite (also called corduroy spar) can be briefly described as a pegmatite rock predominating in K-spar, with the secondary mineral, quartz, forming a distinctive pattern in it. It is a source of feldspar where high K_2O assay is required.

Pegmatite is a prevalent, widely distributed, generally coarse-grained igneous rock from which are obtained predominantly potash feldspar and a certain number of other economic minerals. They occur frequently in association with granites, and usually have major minerals in common with these, but frequently a higher percentage of some (such as K-spar) in large crystals. And, in some instances, there are also additional, often more exotic, minerals present.

Perthite is a microscopic intergrowth of plagioclase in K-spar, having a high K-spar to Na-spar ratio. In graphic granite and in pegmatites, perthite is of common occurrence.

Commercially, *soda spar* is a mixture assaying 7% Na_2O or higher while *potash spar* contains 10% K_2O or higher. The term soda spar has recently changed. Formerly it denoted a higher Na_2O assay than at present. *Pottery spar* is a feldspar product which goes generally into a shaped, fired body where the spar exerts a fluxing action. Such feldspar is usually ground to -200 mesh or finer. The presence of a given level of K-spar is important here, although potash spar is not required in all ceramic applications. *Glass spar* is—with very few exceptions—a soda spar ground to -20 mesh or sometimes as fine as -40 mesh. It is expected to assay a given level of Al_2O_3 —the most important chemical value which the spar furnishes to the melt.

Feldspathic sand is a naturally occurring or processed mixture of feldspar and quartz.

MINERALOGY AND GEOLOGY

Feldspar, or feldspar-plus-quartz, is now being obtained from a limited number of rock types. Most of these have been referred to previously.

The following, as present feldspar sources, appear to merit attention from a mineralogical standpoint:

- 1) pegmatite, including graphic granite;
- 2) "alaskite" as recognized commercially;
- 3) "apfite" in the same sense;
- 4) granite;
- 5) feldspathic sand;
- 6) feldspathic quartzite.

Pegmatite is discussed only briefly here, but several good references are cited in the bibliography.

Generally speaking, feldspathic pegmatite bodies have the following notable characteristics:

*Excerpt from Rogers, C.P., Jr., Neal, J.P., and Teague, K.H., 1983, "Feldspars," *Industrial Minerals and Rocks*, 5th ed., Vol. 1, S.J. Lefond, ed., AIME, New York, pp. 709-722.

- 1) derivation from residual magma solutions;
- 2) wide variety of accessory minerals with frequent evidence of magmatic alteration and replacement;
- 3) considerable variability in shape, size, and extent of body;
- 4) tendency toward a concentric sequence of mineral zones, with varying distributions and ratios of minerals; and
- 5) major minerals in common with associated granites.

Point 4 is commonly seen as the result of successive inward differential crystallization. This phenomenon follows a certain sequence of mineral assemblages (Cameron, et al., 1949).

With these characteristics, involving so many thermal and chemical variables, pegmatites contain feldspars and numerous other minerals in many combinations and a variety of crystal sizes. A list is cited of minor elements which can be found in various pegmatites (Castle and Gillson, 1960):

Sb	Sr	Cb	Zn	Sc	Sn
As	Be	Ta	Li	S	Ti
Bi	Cs	Cu	Mo	Th	Zr
Ba	Ru	Pb	W	U	Rare Earths

In addition, low concentrations of Cr, Co, Hg, Se, Te, V, and precious metals are occasionally found.

The following accessory minerals may be found in pegmatites in addition to the more usual ones (K-spar, Na-spar, quartz, and muscovite) (Williams, et al., 1954):

	Lepidolite	Zircon
	Spodumene	Tourmaline
	Almandine	Topaz
	Spessartite	Epidote
Allanite	Amblygonite	Columbite
Beryl	Fluorite	Tantalite
Apatite	Wolframite	Lithiophilite
Eudialite	Cassiterite	

To these could be added pollucite, petalite, and others.

Distribution of pegmatites in the United States, and their respective sizes and mineralogies, can be further studied by consulting Cameron, et al. (1949). The principal pegmatite regions of the US can be summarized as follows:

- 1) New England: southwestern Maine, New Hampshire, Massachusetts, and Connecticut.
- 2) Southeastern states from Virginia through the Carolinas to Georgia and Alabama.
- 3) Black Hills of South Dakota.
- 4) Rocky Mountain states, especially Colorado and New Mexico.
- 5) Small pegmatite districts in California, Arizona, Idaho, Texas, and Wyoming.

There are scattered pegmatites elsewhere, such as in southeastern Pennsylvania, southeastern New York, northern New Jersey, central Wisconsin, and central Washington.

Where pegmatite consists of large mineral crystals of K-spar, quartz, and not much else, the rock is—or has been—mined and handcobbed for potash feldspar (*block spar*). In other pegmatites, mineral substitutions and alterations have taken place, there are various minor and accessory minerals, and the rock is usually finer grained. Thus it requires beneficiation by relatively fine grinding (–20 mesh), and then by magnetic separation and/or froth flotation, to secure desired concentrates. In addition to feldspar, quartz, muscovite mica, spodumene, pollucite, and other economic minerals are obtained from the finer grained pegmatites. For commercial mining, the best zone or zones of any given pegmatite must be selected to yield the desired minerals in optimum avail-

ability and quality. Pegmatite containing spodumene occurs in contiguous bodies near Kings Mountain, North Carolina, and is an important source of feldspar and feldspathic sand—these being actually secondary to the spodumene content in economic importance. This pegmatite is the characteristic rock of the so-called tin-spodumene belt of the Carolinas. The belt can be briefly described as “a narrow, sinuous zone which strikes northeastward, paralleling in general the layering and foliation of the principal rock units of the area” (Broadhurst, 1956).

In considering theories regarding pegmatite formation, a concept involving mineral deposition from an aqueous or pneumatolytic environment may be of interest. This theory is intermittently referred to by Park, et al. (1964), wherein additional references are given, and by Turner, et al. (1960), dealing with related physical laws.

Graphic granite is cited by Cameron, et al. (1949) as one pegmatite manifestation. Williams, et al. (1954) describe graphic granite by the phrase “a cuneiform intergrowth of quartz and potash feldspar.” This type of intergrowth is supposed to have come about through simultaneous or rapid crystallization from a viscous melt, along with a certain amount of replacement of massive K-spar by quartz. Like coarse-grained pegmatite, graphic granite will yield high-grade potash feldspar if beneficiated by grinding and flotation. If dry ground as is, the resulting feldspar product, being less pure, would be lower grade than fine-ground block spar.

The alaskite commercially mined in the area of Spruce Pine, NC, is defined by Parker (1952) as a Paleozoic igneous intrusive and also a stocklike pegmatite mass of Carboniferous age. Parker divides the intrusives of this area (those covered by his designation “pegmatite”) into (1) some unevenly distributed aplites in the true mineralogical sense, (2) pegmatites of coarse-grained crystalline texture in locations mostly peripheral to the principal finer grained rock, and (3) the principal type, which is characterized by various writers as alaskite or granite. As elsewhere, the coarse-grained pegmatites have yielded commercial hand-mined block spar.

The alaskite is composed, roughly, of the following principal mineral ingredients.

Plagioclase:	45%
Quartz:	25%
Microcline:	20%
Muscovite:	10%

These proportions may vary; there may be less microcline or muscovite and sometimes none. Plagioclase and quartz are nearly always present. The commercially mined rock of the principal mass contains plagioclase-quartz-perthite-muscovite, usually in that order of abundance. In addition there are present minor amounts of garnet, biotite, and apatite plus very small quantities of beryl, tourmaline, epidote, and others (Parker, 1952).

Except for varying textures, the mostly peripheral coarse-grained bodies easily classified as pegmatites differ little in their collective mineralogy from that of the overall central body, leading to the conclusion of derivation from a common magma. Moreover, the prevailing mineralogical ratios of the central body are quite atypical of granite. Grain size of the alaskite is, on the average, between 0.25 and 0.5 in.: considerably coarser than the average granite or granodiorite (Parker, 1952).

The Spruce Pine alaskite has the characteristics of exceptional mineral purity, uniformity, coarse-grained texture,

and large size of deposit, which are sought in commercial ore of feldspar.

The feldspathic aplite of Virginia, previously mentioned, is described by Castle and Gillson (1960) as essentially an intrusive mass having variable texture. It has presumably undergone magmatic alteration from coarse feldspar and is a host rock for titanium minerals not found in true aplite. According to Williams et al. (1954), aplite in the mineralogical sense developed from residual magmas and occurs, associated with pegmatite, as narrow, relatively homogeneous intrusives with such accessory minerals such as garnet, zircon, and tourmaline. These factors, plus differing content of K-, Na-, and Ca-feldspars, indicate that the Virginia rock should not be classified as true aplite. (For an additional reference on this rock, see Ross, 1941).

Granites are extremely abundant, a certain number of them being good sources of high-quality feldspar. Granite is coarse-grained acid plutonic igneous rock. Quartz generally makes up 25 to 30% of the rock; feldspar is the other major component. There is a wide range of minor constituents, among them muscovite, biotite, apatite, zircon, allanite, hornblende, magnetite, epidote, zoisite, and garnet. The feldspar component of granite is principally of the alkali members, which is to say crystalline feldspar containing some ratio of the potassium and sodium feldspars. The remaining feldspar is of the plagioclase series, i.e., a varying ratio of sodium and calcium feldspar is solid solution.

As long as such ores as the pegmatites and the Spruce Pine alaskite are readily available, granite nearby is unlikely to be mined for feldspar. Being generally finer grained than pegmatites, granite must, of course, be also beneficiated by froth flotation. Where granite has been beneficiated for feldspar in the United States, the operation has been in conjunction with quarrying for production of road or dimension stone: fines from such an operation can offer an economic advantage in terms of reduced mining and grinding costs. The granite must be sufficiently coarse-grained so that there is substantial mineral liberation at 40 mesh or coarser. Inclusions of minor, iron-bearing minerals must be at a minimum. Near Pacolet, Spartanburg County, South Carolina, one such granite quarrying operation has in the past furnished tailings which were beneficiated into feldspathic sand. This granite happens to be mineralogically close to the optimum for feldspar beneficiation. The operations are discussed by Eddy, et al. (1972).

Various beach and river sands containing economic amounts of feldspar have apparently acquired the feldspar principally from granitic bodies, and possibly also from feldspathic metamorphic rocks. Basis for this statement is in the assay of feldspar concentrates from these sands. Normal decomposition of feldspar involves first the breakdown and kaolinization of Na-spar, leaving behind a component higher in K-spar. This, if an assay is run on spar concentrate from feldspathic sand and the K_2O is high (perhaps 10% or more), that would indicate either extreme decomposition or that the feldspar originated in a pegmatite. Most concentrates from feldspathic sand, however, usually do not assay over 7% K_2O : considerably below usual pegmatite feldspars, and much more typical of feldspar from partially weathered granite, with part or all of its plagioclase component weathered away. The feldspar in these sands, then, probably is mainly from the original alkaline feldspar of granite.

Since each of the rock types discussed has its own distinctive mineralogy, reflected by the types and ratios of feldspars present, it follows that varying commercial chemical

standards for assorted feldspar uses will be best met by different mineralogical combinations found in aplite, alaskite, granite, feldspathic sand, or pegmatite. (These are cited here in more or less rising order of their K-spar to Na-spar ratio.)

The presence or absence of Ca-spar is usually of slight importance to the feldspar user. Since pure Ca-spar (anorthite) contains a theoretical 36.7% Al_2O_3 , it is welcome in most glass applications. In certain ceramic uses it may need to be limited.

The geology and mineralogy of feldspar are thoroughly discussed by Barth (1969) and the physical and chemical characteristics by Berry, et al. (1959) and Deer, et al. (1966).

DISTRIBUTION AND RESERVES

Feldspar is one of the most plentiful minerals in the earth's crust, occurring in various rock types within a short distance of almost anywhere. Thus, any absolute figure on reserve tonnage is academic. Any estimate of tonnage reserves would have to be relative to the economics of the mineral at the time. The feldspar market in the United States has been highly competitive for many years, and by now the surviving producers have located themselves on ore bodies of the best available quality, i.e., yielding a high percentage of feldspar easily concentrated as a quality product. Mineral purity, size of ore body, and coarse-grained liberation have been paramount considerations. Existing feldspar producers generally have available reserves which are calculated in quarter centuries, if not centuries. There may arise, of course, complications due to zoning or environmental limitations—or perhaps to shipping difficulties. Should such limitations preclude exploitation of many prime quality feldspar reserves, then the vast and widespread granite formations and the unworked alluvial sands may come into the picture. Cost and quality could well be variables of concern, but sheer physical reserves of marketable feldspar are on hand in copious quantity.

One rock type not previously discussed has recently emerged as an interesting potential reserve of potash spar. Located in San Bernardino County, California, this potential ore body is described by Sheppard and Gude (1965) as an altered tuff whose principal constituent is K-spar. It is part of the Barstow Formation and covers a wide area. Its chief disadvantage appears to be a high iron content in much of the feldspar.

FELDSPAR PRODUCTION

Producing Areas, US

In the United States, the state of North Carolina now holds a substantial lead in feldspar production. The state of Connecticut now appears to be second in feldspar production, followed by Georgia and California. Minor quantities of feldspar are shipped from Wyoming.

The Spruce Pine alaskite, measurable in terms of perhaps several square miles in area, irregularly shaped, with associated coarse pegmatites, is the principal feldspar ore of North Carolina. Around Bryson City in Swain County are pegmatites which have in the past yielded block feldspar. In recent years, North Carolina pegmatites in the area of Bessemer City (Gaston County), Lincolnton (Lincoln County), and Kings Mountain (Cleveland County) have been processed by flotation to yield feldspar concentrate. At these places, feldspar is a byproduct of spodumene production. One North Carolina company produces potash feldspar by flotation from a decomposed graphic granite.

South Dakota and Wyoming produce block spar from

pegmatites. This type was formerly produced in Connecticut, but in recent years a shift has been made to froth flotation, working finer grained pegmatites. A deeply weathered pegmatite in Georgia is processed by flotation in order to concentrate potash spar. The Georgia producer is developing a feldspar source in a weathered potash granite in Greene County to supplement present mill feed.

Feldspar Production Outside the US

A partial list of foreign producers would include the flotation plant of Bjorum Sibelco Norfloat A/S and Co. This plant has a capacity of approximately 65,000 tpy, and serves much of Europe and the British Isles. In West Germany, Franz Mandt and Sons operates three feldspar plants, using both imported hand-cobbed feldspar and local feldspathic pegmatites as sources of feed for fine grinding. West Germany also obtains considerable byproduct feldspar from local kaolin operations. In France, Denain-Anzin operates several dry grinding plants, using hand-cobbed spar from the Perpignan area. Maffei and Co. of Italy is one of the largest producers of feldspar in Europe, shipping over 200,000 tpy.

In Mexico, Materias Primas, with headquarters in Monterrey, operates a feldspar plant near Queretaro, using a feldspathic sand as feed; this raw material has been transported to the site by wind.

Many countries in South America produce limited amounts of feldspathic products, the same being true of Africa and Asia.

With the exception of "iron curtain" countries in Europe, it is believed all production not specifically described is by hand selection, rather than by more sophisticated beneficiation techniques.

Aplite Production

The one remaining aplite plant in the United States is located at Montpelier, VA, and is operated by The Feldspar Corp. It produces a low-iron aplite suitable for flint glass and some other glass applications and employs wet methods.

The other former producer at Piney River, VA produced aplite by dry methods suitable for amber and green glass and window glass. The Piney River operation was closed July 1, 1980.

EXPLORATION, MINING, AND PROCESSING

Exploration for feldspar and aplite deposits is fairly simple. A geologist with basic geologic experience in pegmatites, granites, and clays explores potential areas selected by a knowledgeable producer, seeking outcrops and small rock chips appearing as "float." Bulldozers and ditchers may be used to strip a relatively shallow overburden. Diamond drilling has been used to determine depth of a deposit, but is often costly with relation to the information obtained.

In those deposits appearing sufficiently promising, representative samples are collected and refined in a pilot plant—this often being preceded by bench work. The product is

then evaluated by chemical assay and possibly by physical testing: button firing, sample batch runs, etc.

The feldspar industry has learned that, within rather broad limits, feldspathic minerals are suitable for glass and ceramics, provided iron-bearing impurities and the surrounding country rock can be separated from the finished product. Generally the deciding factor is whether, at approximately 20 mesh, or at most 30 mesh, the pure feldspathic mineral can be unlocked from its associated impurities. If it can, the product derived from flotation or magnetic treatment is evaluated as to suitability for available markets.

8. Fluorspar*

Fluorspar is the commercial name for fluorite, a mineral that is calcium fluoride, CaF_2 . The name, derived from the Latin word *fluere* (to flow), refers to its low melting point and its early use in metallurgy as a flux. It is the principal industrial source of the element fluorine.

Cryolite, sodium aluminum fluoride, Na_3AlF_6 , is a rare mineral which has been found in commercial quantities only in Greenland. The natural material has been supplanted by synthetic cryolite for its principal industrial use in the manufacture of aluminum.

HISTORY

Fluorspar was used by the early Greeks and Romans for ornamental purposes as vases, drinking cups, and table tops. Various peoples, including the Chinese and the American Indians, carved ornaments and figurines from large crystals. Its usefulness as a flux was known to Agricola in 16th century Europe.

Fluorspar mining began in England about 1775 and at various places in the United States between 1820 and 1840. Production grew substantially following the development of basic open-hearth steelmaking, wherein it is used as a flux. Use was stimulated by growth of the steel, aluminum, chemical, and ceramic industries, particularly during World Wars I and II. Fluorocarbons entered the picture in 1931. The use of anhydrous hydrogen fluoride (HF) as a catalyst in the manufacture of alkylate for high octane fuel began in 1942.

Differential flotation for separating fluorspar from galena, sphalerite, and common gangue minerals in the 1930s, and the application of heavy-media concentrating methods to the treatment of low-grade ores in the 1940s were outstanding technological advances that facilitated increased production.

Recently, pelletizing and briquetting of flotation concentrates for use in steel furnaces and the development of flotation schemes for beneficiating ores containing abundant dolomite and barite have been major improvements in the industry.

USES OF FLUORSPAR

Fluorspar is used to make hydrogen fluoride, also called hydrofluoric acid, an intermediate for fluorocarbons, aluminum fluoride, and synthetic cryolite. It is used as a flux in the steel and ceramic industries, in iron foundry and ferroalloy practice, and has many minor specialized uses.

Hydrogen fluoride (HF) is produced by reacting acid grade (97% CaF_2) fluorspar with sulfuric acid in a heated kiln or retort to produce HF gas and calcium sulfate. After purification by scrubbing, condensing, and distillation, the HF is marketed as anhydrous HF, a colorless fuming liquid, or it may be absorbed in water to form the aqueous acid, usually 70% HF.

Synthetic cryolite, organic and inorganic fluoride chemicals, and elemental fluorine are made from hydrofluoric acid. The acid itself is important in catalysis in the manufacture of alkylate, which is an ingredient in high-octane fuel for aircraft and automobiles, in steel pickling, enamel stripping, glass etching and polishing, and in various electroplating

operations. The manufacture of one ton of virgin aluminum requires about 23 to 27 kg (50 to 60 lb) of fluorine content in synthetic cryolite and aluminum fluoride. This quantity, through improved technology and recovery practices, is being lowered significantly.

Elemental fluorine is prepared from anhydrous hydrofluoric acid by electrolysis. Gaseous at room temperature and pressure, fluorine is compressed to a liquid for shipment in cylinders or in tank trucks. Elemental fluorine is used to make uranium hexafluoride, sulfur hexafluoride, and halogen fluorides. Gaseous uranium hexafluoride is used in separating U^{235} from U^{238} by the diffusion process. Sulfur hexafluoride is a stable high dielectric gas used in coaxial cables, transformers and radar wave guides. Halogen fluorides have important applications, mostly as substitutes for elemental fluorine which is more difficult to handle.

Emulsified perfluorochemicals, organic compounds in which all hydrogen atoms have been replaced by fluorine, are undergoing investigation as promising blood substitutes. They transport oxygen and, in conjunction with a simulated blood serum, perform many functions of whole blood. With further development, ultimately they may be useful in saving lives of animals and humans in emergencies during periods of acute shortages of natural blood.

Inorganic fluorides are used as insecticides, preservatives, antiseptics, ceramic additives, in electroplating solutions, as fluxes, antioxidants, and many other ways. Boron trifluoride is an important catalyst.

Organic fluorides are volume leaders in the fluorine chemical industry. Fluorinated chlorocarbons and fluorocarbons are prepared by the interaction of anhydrous HF with chloroform, perchlorethylene and carbon tetrachloride, and are characterized by low toxicity and notable chemical stability. They perform outstandingly as refrigerants, aerosol propellants, solvents, and cleaning agents and as intermediates for polymers such as fluorocarbon resins and elastomers.

Fluorocarbon resins are inert compounds with an unusually low coefficient of friction which have found a number of applications for parts that cannot be oiled, such as the bearings inside of automobile doors, for window raising equipment, in small electronic equipment, and for the manufacture of chemical resistant gaskets and valve parts, pipe and tank linings, flexible tubing and containers, and cookware.

In the steel industry, fluorspar is used as a flux in basic open-hearth, basic oxygen, and electric furnaces where it is added to the heats in amounts ranging from 0.9 to 9 kg (2 to 20 lb) per ton of steel produced. The average in the US is currently about 2.7 kg (6 lb) per ton. It promotes fluidity of the slag and thus facilitates removal of sulfur and phosphorus from the steel into the slag. It serves the same purpose in iron foundries, where it is added to the cupola charge in the proportion of around 6.8 to 9 kg (15 to 20 lb) per ton of metal melted.

In the ceramic industries, fluorspar is used to make flint glass, white or colored opal glasses, and enamels. Flint glass mixtures commonly contain 3% fluorspar. Opal glasses, containing 10 to 20% fluorspar, are used in containers for foods, drugs and toiletries, and in ornamental glassware and laboratory and restaurant fixtures. Opaque enamels are used to cover steel stoves, refrigerators, cabinets, bathtubs, and cook-

*Excerpt from Fulton, R.B., and Montgomery, G., 1983, "Fluorite and Cryolite," *Industrial Minerals and Rocks*, 5th ed., Vol. 2, S.J. Lefond, ed., AIME, New York, pp. 723-744.

ing ware and for facings on brick and tile, and other structural materials. Fluorspar makes up to 3 to 10% of the weight of the enamel. Many types of welding rod coatings incorporate fluorspar or fluorspar mixtures. Ceramic grade fluorspar is used in the manufacture of magnesium and calcium metals and in the preparation of some manganese chemicals.

Lower grades of ceramic spar are used in making fiber-glass insulation, in zinc smelting, as a clinkering aid in the manufacture of portland cement, as an inhibitor of vanadium green scumming in the manufacture of buff-faced brick, and as an abrasive on certain types of sandpapers. Various grades of fluorspar are used in electric furnace manufacture of calcium carbide, in making electrodes for arc lamps, and as a bonding material for abrasive wheels, among numerous minor uses.

GEOLOGY

Composition and Properties

Theoretically pure fluorite contains 51.1% calcium and 48.9% fluorine. Substitution of small percentages of cerium and yttrium for calcium has been noted. Inclusions of gases and fluids, such as petroleum and water, and of solid minerals such as pyrite, marcasite, and other sulfides are common. Free fluorine is present in some crystals. The fluorspar of commerce contains attached and admixed mineral impurities, such as calcite, quartz, barite, celestite, various sulfides, or phosphates.

Fluorite tends to occur in well-formed isometric crystals, forming cubes and octahedrons. It also occurs in massive and in earthy forms, and as crusts or globular aggregates with radial fibrous texture. Crystalline fluorspar exhibits a great range of colors, from colorless and waterclear to yellow, blue, purple, green, rose, red, bluish and purplish black, and brown. The colors may occur in alternating bands parallel to cube faces. They may be altered by exposure to X-rays, heat, ultraviolet light, and pressure. Colors are caused by a variety of factors including the presence of trace impurities and displaced ions in the lattice. Long exposure to sunlight, such as occurs on mine dumps, frequently results in the fading of the original coloration.

Some varieties fluoresce blue or violet under ultraviolet light or cathode rays. Some specimens phosphoresce when heated or after exposure to sunlight or ultraviolet light, and some exhibit triboluminescence.

The mineral has a hardness of 4, and is the type mineral of that hardness on the Mohs' scale. Its specific gravity is 3.18 when crystalline, but ranges from 3.01 to 3.6 in various forms. The luster is vitreous. The mineral has perfect octahedral cleavage, and "diamonds" made by knocking the corners off of cubic crystals are seen in many collections.

When pulverized and treated with sulfuric acid, fluorite decomposes into gaseous hydrogen fluoride and calcium sulfate, which is the fundamental reaction in the production of hydrofluoric acid. When added to metallurgical slags, it imparts greater fluidity at lower temperatures making it valuable in steelmaking and ferrous and nonferrous foundry practice. In ceramic mixes it promotes crystallization around individual centers, and thus is useful in making opal glasses. Crystalline fluorite has a very low index of refraction ($n = 1.4339$), low dispersion, is isotropic, and has an unusual ability to transmit ultraviolet light. These are the properties which make it useful in optical systems as prisms and as components of high quality, special-purpose lenses. Synthetic fluorite has replaced the natural mineral for optical uses.

Modes of Occurrence

Fluorite occurs in a wide variety of geological environments, evidencing deposition under an extended range of physical and chemical conditions. At one extreme it is present as an accessory mineral in granites and related igneous rocks; while at the other extreme, it is found as crystals in geodes and as botryoidal linings in limestone caves.

From an economic standpoint, the most important modes of occurrence of the mineral are:

- 1) Fissure veins in igneous, metamorphic, and sedimentary rocks.
- 2) Stratiform replacement deposits in carbonate rocks.
- 3) Replacements in carbonate rocks along contacts with acid igneous intrusives.
- 4) Stockworks and fillings in shattered zones.
- 5) Deposits at the margins of carbonatite and alkaline rock complexes.
- 6) Residual concentrations resulting from the weathering of primary deposits.
- 7) Occurrences as recoverable gangue in base metal deposits.

Less common modes, in some places commercially important, include:

- 8) Fillings in breccia pipes.
- 9) Fillings in open spaces.
- 10) Pegmatites.

Least common but of potential importance are:

- 11) Deposits in lake sediments.

Fissure Veins: Fissure veins, usually along faults or shear zones, are the most readily recognized form in which fluorspar deposits occur the world over. Silica, calcite or other carbonates, iron, lead, and zinc sulfides, and barite are the typical associated minerals. In some vein deposits as in the Rosiclare district of southern Illinois, fluorite appears to have replaced a prior vein filling of calcite. Along some veins in carbonate rocks, fluorspar has replaced the wall rock at intersections with favorable beds, providing large minable tonnage mined from some deposits. Although vein structures are remarkably persistent, the fluorspar itself commonly occurs as lenses or ore shoots separated by barren or poorly mineralized portions of vein. Ore shoot widths of 0.6 to 9 m (2 to 30 ft) and lengths of 61 to 305 m (200 to 1000 ft) are common, but there is great variation from deposit to deposit. Vein systems may be up to several miles in length, and ore may be present to depths of 305 m (1000 ft) or more below the surface. The CaF_2 content of minable portions of veins normally ranges from 25 to 80%, although grades above 90% occur in limited areas.

Some of the world's great vein deposits include the Osor deposit in northeastern Spain, the Torgola deposit in northern Italy, the Muscadroxiu-Genna Tres Montis vein system in Sardinia, the Longstone Edge-Sallet Hole deposit in England, and the Rosiclare-Goodhope vein system in southern Illinois.

Stratiform Deposits: Stratiform, manto, or bedded deposits occur in carbonate rocks. Certain beds are replaced along or adjacent to structural breaks such as joints or faults. This relationship to structural features is very clear in some deposits, but obscure in others. Frequently there is a sandstone, shale, or clay capping. Typically there is evidence of loss of volume in the replaced zones with attendant development of gentle synclinal structures in overlying strata or of collapse structures, sometimes pipelike in shape. In some districts, as in southern Illinois, no connection is recognized between the mineralization and any igneous activity, whereas

in others, such as the Encantada district in northern Coahuila, Mexico, the presence of rhyolite plugs and sills in the general vicinity of the spar deposits, and the association of spar with rhyolite injections along bedding planes, suggests an association. Stratiform deposits are known in many parts of the world and are particularly well developed in the Cave in Rock district of southern Illinois, in the northern part of the State of Coahuila in Mexico, and in the Ottoshoop (Zeerust) District of Transvaal in South Africa. In Illinois the deposits range from a few centimeters to 6 m (few inches to 20 ft) thick, 15 to 152 m (50 to 500 ft) wide, and are up to 7 km (4½ miles) long. In Coahuila the individual ore bodies are smaller but relatively more numerous and widespread. In the Ottoshoop District bedded deposits occur in an area 16 km (10 miles) long and 9.7 km (6 miles) wide in a dolomite facies underlying a prominent chert bed.

In stratiform deposits, textural features of the parent rock such as sedimentary banding are commonly preserved. Frequently associated with the banded ore is a massive crystalline type which appears to have filled open spaces left from the dissolving of limestone by the ore-bearing solutions or their precursors. Minerals accompanying fluorspar in stratiform deposits are calcite, dolomite, quartz, galena, sphalerite, pyrite, marcasite, barite, and celestite. CaF_2 content in minable deposits ranges from 15% upward. A few ore bodies in Illinois yield direct shipping metallurgical grade fluorspar containing 85% or more CaF_2 .

Replacement Deposits: Replacement deposits in carbonate rocks along contacts with intrusive rhyolite bodies are well developed in the Rio Verde, San Luis Potosi, and Aguachile districts in Mexico. They include some of the largest and highest grade fluorspar deposits. The fluorspar is not thought to be contact metamorphic in origin, but introduced later, following the contact zone as a conduit replacing the limestone outward from the contact, either massively or selectively along certain beds. At Aguachile, cross sections show ore shoots resembling one side of a Christmas tree.

Stockworks: Fluorspar often occurs as stockworks and fillings in shear and breccia zones. Many occurrences in the American West are of the stockwork type and, though wide, usually have low overall CaF_2 content. Deposits in the Zuni Mountains of New Mexico and near Jamestown, CO, are examples. The Zwartkloof deposit in the Transvaal Province of South Africa consists of three vertical breccia zones in an east-west line in felsite containing stockworks of fluorite-carbonate veins. The largest zone is 61 by 183 m (200 by 600 ft) in plan and persists to 914 m (3000 ft) below the surface. The fluorspar grade is about 14%. The Buffalo deposit, near Naboomspruit in the Transvaal, consists of a network of fluorspar veinlets in sill-like bodies of fine-grained pink granite which are inclusions in coarse red granite of the Bushveld complex.

Carbonatite and Alkaline Rock Complexes: Fluorspar is a common mineral in carbonatite and alkaline rock complexes, rarely in sufficient abundance to be economic. The Okorusu deposit in South-West Africa (Namibia) of this type consists of a number of bodies of fluorspar in limestones, quartzites, and related rocks which have been intruded and metamorphosed by an alkaline igneous rock complex including a nepheline syenite stock. The fluorspar replaced bedded and brecciated limestone, marble, and quartzite, forming large lenticular masses. Apatite and quartz are abundant accessory minerals. At Amba Dongar, India, veins and replacement bodies of fluorspar occur in carbonate rocks bordering ankeritic carbonatite intrusives. Fluorite is also present in the carbonatite itself.

Residual Deposits: Concentrations of fluorspar in clayey and sandy residuum resulting from surficial weathering of fluorspar veins and replacement deposits in some places are sources principally of metallurgical spar. This category includes detrital deposits blanketing the apex of veins, as well as deeply weathered upper portions of the veins themselves extending to depths of 30.5 m (100 ft) or more. Such deposits were of major importance in Illinois and Kentucky. Similar deeply weathered ore has been mined in England, Thailand, and the Asturias district of northwestern Spain. Weathered residuum, called *kokoman*, is mined in the Marico district in South Africa, where it is the result of the weathering of gently dipping replacement bodies.

Gangue Mineral: Fluorspar occurs as a major gangue mineral in lead-zinc veins in many parts of the world, and in some, averaging 10 to 20%, is economically recoverable. Acid grade fluorspar is produced on a large scale from lead-zinc mill tailings near Parral in Mexico.

Breccia Pipes: Fluorite occurs in breccia pipes in the Thomas Range, Utah and near Beatty, NV. Pipes in the Thomas Range are circular to oval in plan, up to 46 m (150 ft) in diameter and over 61 m (200 ft) in depth, and are formed in dolomite by replacement along shattered zones associated with faults and intrusive breccias. Fluorspar occurs as soft friable masses and in boxworks of fine-grained more resistant veinlets, and is nearly unrecognizable. At the Daisy mine near Beatty, fluorspar replaces brecciated dolomite in pipelike bodies bounded by gouge zones along two sets of intersecting faults.

Fillings in Open Spaces: Fluorspar occasionally partially fills open spaces, both in veins and stratiform deposits. Spectacular examples of this type occur in the San Vicente district of northern Coahuila, where fluorspar occurs in veins and mantos as pure massive incrustations of mamillary, stalactitic, and stalagmitic forms. The Fluorspar-Gero-Penber vein system of the Northgate mine in Colorado is a similar occurrence where fluorspar occurs in botryoidal layers on the walls of open fissures and as concretionary coatings surrounding loose fragments of country rock. Lower parts of open areas of these fissures are partly filled with concretionary pebblelike masses, in places cemented into porous, rubbly aggregates.

Pegmatites: Many pegmatites contain minor amounts of fluorspar. Grade was high enough to support a mining operation at the Crystal Mountain occurrence in Montana, where three large tabular bodies of massive fluorspar containing minor amounts of biotite, quartz, feldspar, and other igneous-type accessory minerals, occur in coarse-grained biotite granite.

Lake Sediments: Fluorspar occurs in unconsolidated clayey and sandy pyroclastic sediments in the beds of former lakes near Castel Giuliano, about 40 km (25 miles) north of Rome, Italy. Fluorine of volcanic origin permeated the lake sediments resulting in deposition of minute disseminated crystals of fluorspar, which make up as much as 50 to 60% of the clayey parts and 15% of the sand parts of the deposits. It is accompanied by barite, apatite, calcite, dolomite, and opal.

DISTRIBUTION OF DEPOSITS

Fluorspar deposits occur on every continent. Major producers include the United States, Mexico, Spain, England, France, Italy, South Africa, China, Thailand, Mongolia, and the USSR. Lesser producers include Argentina, Brazil, Bulgaria, Czechoslovakia, Kenya, Tunisia, Morocco, West Germany, East Germany, Romania, India, and Korea.

North America

Canada: The only large production in Canada was from the St. Lawrence area of the Burin Peninsula in southern Newfoundland, which yielded over 2.7 Mt (3 million tons) of ore from 1940 until operation ceased in 1978. Other deposits occur in Ontario at Madoc and near Wilberforce and Cobden; at Rock Candy and Birch Island near Kamloops and near Quesnel Lake in British Columbia; along the Lower Laird River in northern British Columbia; and at Lake Ainslie on Cape Breton Island in Nova Scotia.

On the Burin Peninsula, fluor spar occurs in veins in granite and rhyolite porphyry along steeply dipping faults. Average thickness of higher grade veins is 0.9 to 1.5 m (3 to 5 ft) and of lower grade veins is 4.6 to 6 m (15 to 20 ft). Some veins have been traced for more than a mile.

Veins at Madoc are small and have been worked principally in wartime. The veins at Lake Ainslie are low grade fluor spar with associated abundant barite. A deposit at Birch Island remains undeveloped with reserves said to be 1.4 Mt (1.5 million tons) of 29% CaF_2 grade. Bedded deposits on the Lower Laird River near Mile 497 on the Alaska Highway in northern British Columbia have not proved to be of current commercial interest. Two low grade fluorite deposits near Likely, BC, were reported to be under exploration early in 1981.

Mexico: Mexico is the world's largest producer of fluor spar. Important deposits occur in San Luis Potosi, Coahuila, Chihuahua, and Guanajuato.

Many types of deposits are mined. In the Musquiz district of northern Coahuila, mantos in Cretaceous limestones are most important. Northwestern Coahuila has vein deposits and replacement deposits in limestone associated with rhyolite sills and plugs. Deposits in the Paila district of central Coahuila are veins. In San Luis Potosi and adjoining Guanajuato are several large replacement deposits in limestone associated with rhyolite intrusives. Numerous vein deposits occur in Chihuahua, but its principal production is acid grade concentrate recovered from sulfide mill tailings near Parral.

United States: Alaska—The Lost River deposit, located in the western portion of the Seward Peninsula 136.8 km (85) miles northwest of Nome, was worked intermittently for tin from 1904 to 1955 and has since been explored for fluor spar, beryllium, and tin. Fluor spar-tin-tungsten-beryllium mineralization occurs in acidic dikes, in skarn deposits along granite-limestone contacts, and brecciated limestone adjacent to thrust faults. Mineralization in one zone was reported to be 24.5 Mt (27 million tons) grading 16.3% CaF_2 , 0.15% tin, and 0.03% tungsten. Fluor spar also occurs in six other zones in the district (Anon., 1972), but there has been no production.

Arizona—Although 56 occurrences of fluor spar were listed in one summary (Van Alstine, 1969) and 96 in another (Elevatorski, 1971), to date cumulative production has probably been less than 45 kt (50,000 tons). Deposits are widely scattered in the southern half of the state, principally as small epithermal veins in fissures and brecciated zones along faults in intrusive, metamorphic, and sedimentary rocks. No large replacement deposits have been found. Fluorite occurs mostly with calcite and quartz in non-metaliferous veins, although in the Castle Dome district it is a gangue mineral along with barite, quartz, and calcite in veins which were mined on a small scale for their lead-silver content.

The Castle Dome, Duncan, Sierrita Mountain, Tonto Basin, and Whetstone Mountain districts have been producers. The Lone Star mine in the Whetstone Mountain district

yielded 9 kt (10,000 tons) of metallurgical spar in 1967, but then closed down.

California—Although there are many occurrences of fluor spar in California, only small amounts have been produced for ceramic and metallurgical purposes. Metspar was produced on a small scale from the Clark Mountain area of San Bernardino County in the 1950s and 1960s. California occurrences have been described by Chesterman (1966) and Elevatorski (1968).

Colorado—Colorado in some years ranked second in annual production, after Illinois. Aggregate production of crude ore to the present is estimated at about 2.3 Mt (2.5 million tons).

A total of 63 occurrences have been identified in the state (Van Alstine, 1964), including five major districts, all now idle. Northgate and Jamestown districts were the largest and most recently closed. The others are Browns Canyon, Poncha Springs, and Wagon Wheel Gap.

In the Jamestown district, fluor spar occurs in pipe-like bodies and breccia zones in granite and granodiorite, and in associated veins. Output of the Burlington mine was treated at the former Valmont Mill near Boulder. Other mines include the Argo, Emmett, and Blue Jay, ore from which was concentrated to acid grade in a mill, located at Jamestown. Neither mill exists now.

At Northgate, fluor spar occurs in veins in shear and breccia zones in granite and schist, and has been surface mined and underground. During World War II the district produced metspar. Exploratory drilling continues from time to time and may result in reopening as prices rise.

The Browns Canyon district included a number of mines, developed on veins in rhyolite and in granite. The Wagon Wheel Gap mine was on a vein in a sheeted zone in rhyolite yielding metspar.

Idaho—The principal deposits of fluor spar in Idaho are in the Bayhorse-Keystone Mt. area of Custer County, southwest of Challis, and in the Meyers Cove, Big Squaw Creek, and Stanley areas (Anderson, 1964).

The Bayhorse dolomite replacement deposits, as outlined by core drilling and partially developed for mining, may exceed 2.9 Mt (3.2 million st) of 36% CaF_2 , with a 25% grade cutoff. Other deposits, both vein and replacement, occur in the Bayhorse district and on adjoining Keystone Mt. The district has potential if production economics can offset freight disadvantages.

At Big Squaw Creek, a vein is exposed in the northeast canyon wall of the Salmon river west of Shoup. At Stanley, fluor spar occurs in shear zones in granite and volcanics.

Illinois-Kentucky—Current production is focused at two flotation mills situated in an area of 1813 km (700 square miles) in southern Illinois and adjacent Kentucky which for a number of years was the world's largest producer (Baxter, et al., 1973).

Vein deposits are the most numerous, but since 1950 the bedded deposits near Cave in Rock, IL, have been the source of most of the district's output, and outrank the vein deposits in terms of total all-time district production. Recently production from vein deposits has resumed importance as some of the older bedded deposits have been depleted.

In addition to the major district, a small production has been recorded from veins southwest of Lexington, in central Kentucky.

Vein deposits of the Illinois-Kentucky district occur along an extensive and intricate system of faults in sedimentary rocks of Mississippian Age. Most of these faults are the

steeply dipping normal type, trending northeast, with displacement ranging from a few meters (feet) to over 305 m (1000 ft). The most important deposits are on faults of 15 to 152-m (50 to 500-ft) displacement. Veins range in width up to 9 m (30 ft) and to as much as 18 m (60 ft) in exceptional cases. They have been mined for 274 m (900 ft) vertically and for 3.2 km (2 miles) in length. Veins pinch and swell horizontally and vertically with the proportion of fluorspar to total vein material ranging from 0 to 100% within short distances. Near the surface and to depths as great as 76 m (250 ft), the veins contain much clay owing to the dissolving of vein calcite and limestone wall rock by circulating ground water leaving the argillaceous material in the limestone behind. Strong walls are found at depth in most places. A large inflow of water at high pressure was characteristic of the deeper mines, particularly at Rosiclare.

Major replacement deposits occur in Illinois northwest and north of the village of Cave in Rock; others occur in Kentucky south of Carrsville and near Hampton in Livingston County. The Cave in Rock group of mines occupies a zone of minor structural disturbance 1.6 km (1 mile) wide and over 9.6 km (6 miles) long, paralleling a major northeast trending fault which has maximum displacement of about 305 m (1000 ft). The deposits lie along one or both sides of minor fractures and small faults and are characteristically long and narrow. Major deposits occur along fracture-fault systems with less than 0.3 m (1 ft) of displacement. Widths of 15 to 46 m (50 to 150 ft) and thicknesses of 0.9 to 4.6 m (3 to 15 ft) are typical. Maximum widths of 99 to 107 m (325 to 350 ft) have been found. Lengths are mostly 61 to 457 m (200 to 1500 ft). One ore body is known to extend continuously for at least $4\frac{1}{2}$ miles. The deposits occur through a vertical range of about 55 m (180 ft) in four preferred sets of limestone beds and follow these beds down dip from the outcrops (which were discovered originally in a prominent bluff) to depths well over 1000 ft.

Residual deposits have been less important producers, but have yielded high quality fluorspar. These "gravel spar" deposits are as much as 18 m (60 ft) wide and extend to depths of a hundred feet or more. The fluorspar occurs as weathered fragments from the size of boulders down to sand grains dispersed in a clayey matrix.

Montana—Most of the fluorspar production has come from the Crystal Mountain deposits near Darby in Ravalli County. The deposits of massive fluorite in granite and metasediments were discovered in 1951 and developed into one of the nation's major metallurgical grade fluorspar mines.

The mine was a side-hill benched open pit at the 2134-m (7000-ft) elevation on Sapphire Mt. Ore was mined, hand-sorted, and sized at the mine continuously from 1952 to 1973. This roughly concentrated ore was hauled 40 km (25 miles) by truck to Darby, where finished concentration was accomplished in a 54 t/h (60-ton per hr) heavy-media cone plant. The metspar was shipped by rail to steel plant consumers and government stockpiles.

Shipments from the accumulated fines at the heavy-media plant continued from 1973 to 1980 to briquetting plants serving the steel industry. Production from 1952 to 1980 totaled 513.5 kt (566,000 tons) of which 471.7 kt (520,000 tons) was metspar, 1.8 kt (2000 tons) was metspar-sized jig product 6.3×12.5 mm ($\frac{1}{4} \times \frac{1}{2}$ in.), and 39.9 kt (44,000 tons) was submetgrade fines. Mining and shipment of fines resumed in 1981.

Numerous other fluorspar occurrences have been recorded in Montana but have no production history. Fluor-

spar occurs as gangue in metalliferous veins in marginal portions of the Boulder batholith in west-central Montana, and is present as veins and replacement seams in intrusive syenite and in limestone in several areas characterized by alkalic intrusives in the north-central part of the state.

The presence of fluorspar has been used as a guide to gold deposits. In the Old Glory deposit in the Pryor Mountains, fluorspar occurs with the uranium mineral, tyuyamunite, replacing limestone in brecciated and cavernous portions of the Madison limestone.

Nevada—Fluorspar became commercially important in Nevada in 1919 when the Daisy mine near Beatty began its long productive life. Nevada deposits are described in a recent publication by Papke (1979). Most of the 62 deposits he describes lie in a broad, arcuate band across the southern part of the state, and northward through the central part. Total production has been about 522 kt (575,000 st) most from the Daisy (Crowell) mine in southern Nye County, the Baxter (Kaiser) mine in northeastern Mineral County, the Goldspar mine near the Daisy, and the Carp (Wells Cargo) mine in southeastern Lincoln County. About 19 other deposits have had some production, but only the Daisy mine is active. More than a fourth of the deposits are in the Quinn Canyon and Adaven district in the southeastern part of the state, but the small size of the deposits and remoteness of this area has hindered their development. Small metspar shipments have been made from Caliente.

Deposits are hydrothermal or pyrometamorphic. They occur as replacement bodies, veins, replacement and/or filling in jasperoid bodies, stockworks, and breccia pipes. The Daisy deposit is mined underground, with total past production of about 204 kt (225,000 st). It consists of irregular, generally steeply dipping, structurally complex replacement bodies in dolomite. The ore is soft, friable, and relatively low in silica. Most has been used as metspar. Some has been shipped to a southern California cement producer. The Baxter deposit, a vein in andesitic volcanic rocks, developed to a depth of 183 m (600 ft), had a total mine production of 165 kt (182,000 st), of which two-thirds was made into acid-grade concentrate in a mill operated from 1952 to 1957 by Kaiser Aluminum and Chemical Corporation at Fallon, NV. The Goldspar and nearby Mary deposits are breccia pipe and replacement bodies in dolomite. All the fluorspar from these surface mines was used in making cement. At the Carp mine an estimated 40.8 kt (45,000 st) of metspar was produced in four surface mines. The ore came from nearly flat, mantolike replacement bodies, generally concordant with bedding of the dolomite host rock.

New Mexico—There are numerous occurrences of fluorspar in New Mexico but production has been small. Van Alstine (1965) listed 65 areas in the central, north central, and southwestern parts of the state. The fluorspar map MR-60 of the USGS and accompanying tabulation in 1974, by Worl, Van Alstine, and Heyl, classified some 51 locations as to type, tonnage, and associated minerals.

Eight areas each produced at least 15 kt (20,000 tons) of crude ore and cumulative total statewide production has probably been about 635 kt (700,000 tons). Production peaked in World War II, when New Mexico was the fourth largest producing state after Illinois, Kentucky, and Colorado.

Most production came from the Zuni Mts., Sierra Caballos Mts., Gila district, Burro Mts., Cooks Peak, and from Fluorite Ridge and Tortugas near Las Cruces.

In the Zuni Mts., the "27" vein deposits were the most

productive, with the Mirabal deposit contributing. Until closed in 1953, these had produced totally about 203 kt (224,000 tons) of ore.

In the Cooks Peak district near Deming, White Eagle, Greenleaf and others in the Fluorite Ridge district, and Burro Chief and Shrine deposits in the Burro Mts. were important producers. All are vein deposits in brecciated or fractured zones along faults in igneous rocks. The Lyda K Mine, south of Truth or Consequences, is a siliceous vein in Precambrian granite. The Ruby mine north of Las Cruces contains veins in limestone near an igneous contact. At Chise small manto replacement bodies occur in limestone beds. The Bishops Cap deposit is a vein in limestone, with some adjacent replacement ore. In the Hansonburg district, east of San Antonio, fluorite occurs with lead and barite as vug filling in brecciated limestone.

The Salado deposit, southwest of Truth or Consequences, consists of tabular masses of fractured and brecciated jasperoid with the fluorspar forming a filling and cement. Between 2.3 and 2.7 Mt ($2\frac{1}{2}$ and 3 million tons) of low-grade mineralization have been estimated from drilling results. A thickness of over 12 m (40 ft) in places would permit open-pit mining, with little overburden. Difficult flotation metallurgy, low grade, and remoteness from market have inhibited development.

Oregon—Near Rome in the southeastern part of the state, fluorspar occurs as nearly spherical grains in volcanic tuff, tuffaceous mudstone, and mudstone of Tertiary lake deposits (Sheppard and Gude, 1969). The fluorspar content reaches 16% in some zones, but is generally much lower. The tonnage of contained fluorspar is estimated at 11 Mt. Because of very fine particle size, concentration to acceptable grade has not proved practical.

Tennessee—A small amount of metspar was produced from a small fissure vein in limestone in the central part of the state, where it occurs with barite and sulfides (Jewell, 1947).

Fluorite has been noted as a gangue mineral in zinc deposits near Carthage, locally comprising 12 to 15% of the ore but averaging much less.

A drilling program in the Sweetwater area indicated fluor-spar-zinc-barite mineralization several hundred meters (hundred feet) below the surface in buried karst breccia zones similar to the Mascot district, TN zinc deposits. Exploratory drifting was done from a 183-m (600-ft) shaft sunk in 1979, now plugged.

Texas—Metallurgical grade fluorspar production began in 1971 in the Christmas Mts. south of Alpine from bedded limestone replacement mantos adjacent to intrusive rhyolite bodies. In late 1980, a 274-m (900-ft) decline was sunk beneath a laccolithic structure where exploration and development work continue.

In the Eagle Mts. southwest of Van Horn, fluorspar occurs as replacement of limestone and as fissure deposits in rhyolite. In the period 1942 to 1950, about 13.6 kt (15,000 tons) of metallurgical gravel and acid grade were produced.

Utah—Most of the deposits are located in the west-central part of the state in the Spor Mountain, Indian Peak, Pine Grove, and Star districts. The Spor Mountain district in the Thomas Range northwest of Delta has been the most consistent producer. The deposits are classified as pipes, veins, and disseminated bodies in dolomite and volcanic rocks. Most of the production has come from the pipes. The most productive mines have been the Lost Sheep, Fluorine Queen, and Bell Hill.

In the Indian Peak district veins occur along faults in

volcanic rocks. The Cougar Spar and Blue Bell mines were World War II producers of metspar. Small production has also been recorded from the Pine Grove and Star districts, and from the Rain Bow mine in Millard County and the Silver Queen mine in Tooele County.

Cumulative Utah production of crude ore to date is estimated to have been 226.8 kt (250,000 tons).

Washington—A small production of metspar has come from the Mitchem mine near Keller, in Ferry County.

Wyoming—There are reports of fluorspar in Crook and Albany counties.

Central America: Occurrences have been reported in Honduras and Guatemala, but details are not available.

South America: Argentina—Vein deposits have been mined intermittently in the Sierra Comechigones, 48 km (30 miles) northwest of Cordoba and others developed for production in the southern part of Rio Negro province and the adjoining northern part of Chubut. In recent years, metspar has been produced from a group of veins in the Sierra Grande district of Rio Negro, including the Delta vein, reportedly with 3.6 Mt (4.0 million tons) of drill-indicated ore of 51% CaF_2 grade. In Chubut a number of veins have been discovered in areas west of Puerto Madryn.

Brazil—Principal deposits are in the vicinity of Criciuma in the Santa Catarina province of southern Brazil. Small-scale production has been reported from deposits in the provinces of Rio Grande do Norte, Paraiba, and Bahia.

In the Criciuma district, known deposits are not large and continued output will depend on the discovery of new reserves and the resolution of water problems.

Chile—Small tonnage of fluorspar has been produced from veins in granite in the Province of Coquimbo. One deposit, the Mercedes mine, is near the village of Paihwan.

Europe: France—Important deposits occur in the departments of Haute-Loire, Pyrenees-Orientales, Var, Tarn, Saone-et-Loire, and Puy-de-Dome. Details have been described in a series of articles by Chermette (1972-1973, 1979).

Epithermal vein deposits occur in the Morvan, Auvergne, Limousin, and Albi districts of the Massif Central, the Maures and Esterel districts of the Mediterranean coastal area northeast of Toulon, in the eastern Pyrenees west of Perpignan, and in the Vosges. The vein deposits contain about 50% CaF_2 , 20% silica, 5 to 50% barite, and 3 to 5% sulfides. Stratiform deposits with about 35% CaF_2 and 15% barite occur in the Morvan district. Deposits having stratiform characteristics are important producers in the Escaro district in the Pyrenees southwest of Perpignan. Deposits at Le Beix, Chavaniac, and Le Maine in the Massif Central are exhausted. La Charbonniere and Langeac have also closed. Fonte Sante (near Cannes in Var), Le Burc (near Albi in Tarn), Montroc (near Albi), Escaro and Chaillac continue in operation. Fonte Sante is noteworthy for the economic occurrence of sellaite (MgF_2) which is blended with the fluorspar product and is used at the Lyons hydrofluoric acid plant.

Germany, East—East Germany is estimated to produce about 100 kt/a of fluorspar. Deposits are in Saxony, Thuringia, and Anhalt, but details are lacking.

Germany, West—Production is derived from vein deposits in the Todtnau, Hesselbach, Oberwolfach, and Pforzheim districts in the Black Forest region in the southwest, and in the Naaburg and Sulzbach districts in Bavaria.

Greece—Fluorspar occurs as a gangue mineral in the silver ores of Laurium, but Greece imports its requirements.

Italy—Mines in Sardinia are the principal producers. Smaller outputs have come from Brescia, Trento, Bolzano,

and Bergamo in northern Italy. The Genna Tres Montis-Muscadroxu-S'Acqua Frida vein system in southern Sardinia near the village of Silius is credited with 8 Mt of ore reserve averaging 40 to 45% CaF_2 , making it one of the world's largest deposits. Vein widths are 5 to 8 m. Barite and galena are recoverable accessory minerals. Numerous other vein deposits and a skarn deposit occur in southern Sardinia.

In northern Italy important deposits include Prestavel and Vallarsa near Bolzano, Torgola near Brescia, and Camerata Cornello near Bergamo.

The Pianciano deposit in the Castel Giuliano area 40 km northwest of Rome consists of fluor spar impregnating lake beds of volcanic ash (Spada, 1969). The fluor spar content, ranging from 20 to 55%, was derived from volcanic emanations along with barium, strontium, and phosphorous. The fluor spar is too fine-grained to be recovered by flotation, but tests indicate a possibility of producing metallurgical grade by hydrocyclone separation.

Norway—Veins are reported in the Buskerud, Telemark, Vest Agder, and Drammen regions west and southwest of Oslo. The Lassedal mine near Kongsberg was formerly a producer.

Spain—Principal deposits are in the Asturias region of northern Spain near the ports of Ribadesella and Aviles; in the southeast near the port of Almeria; and in south-central Spain near Seville and Cordoba. Deposits are both veins and replacement bodies. Acid-grade material is derived in the retreatment of old lead mine wastes in the Almeria-Berja area. Seven companies have produced acid grade, four in Asturias, two in the Seville-Cordoba region, and one near Berja. Grades of ore range from 40 to 45% for some of the vein-mines, down to 15 to 20% in the case of old lead mine waste. The large Osor vein in Gerona is exhausted.

Sweden—The sole producer in Sweden, the government-owned Yxsjöberg mine near Ludvika, 200 km northwest of Stockholm, where fluor spar occurs with tungsten and copper, closed in 1977. Other deposits have been reported between Branteriks and Onslunda in Skane in southern Sweden. The Osterlen district was formerly a small producer.

Switzerland—Occurrences are known, but none of commercial importance.

United Kingdom—Among numerous fluorite occurrences in the United Kingdom, present operations are located in the Southern Pennine Orefield of north Derbyshire and in the Northern Pennine Orefield of west Durham. Production comes from fissure veins and bedded replacement deposits, together with associated old lead mine waste and tailings dumps. The deposits occur in rocks of the Carboniferous Limestone Series (Mississippian). Ore is mined both underground and open pit. The deposits contain variable amounts of galena, sphalerite, calcite, barite, quartz, and iron sulfides. Some were originally mined for lead, even before written record.

USSR and Soviet Bloc—Deposits are reported in the Transbaikalian, Tashkent, and Yaroslavl regions. Czechoslovakia produces about 90 kt/a from deposits in Bohemia. Mongolian deposits are southwest of Ulan Bator in the Dorono Gobi district. Romania produces about 20 kt/a; Bulgaria about 25 kt/a, and Yugoslavia has a small production.

Africa: Angola—Deposits are reported in Angola, but details are lacking.

Kenya—A 100% government-owned acid grade mill, formerly jointly owned with IMC and Bamburi Portland Cement, produces concentrates relatively high in P_2O_5 from epithermal vein and replacement deposits in the Kerio Valley,

about 130 km northwest of Nairobi. Ore ranging from 30 to 45% CaF_2 is mined open pit.

Other similar deposits are reported along the Rift structure.

Malawi—Exploration for fluor spar deposits related to carbonatite structures has been reported; five such occurrences are noted by Van Alstine and Schruben (1980).

Morocco—The El Hammam deposit near Meknes is a nearly vertical vein on an east-west fault in sericite schist, grading about 45% CaF_2 . Three other deposits are recognized in this region. Other veins occur in the Djebel Tirremi area, 10 km northeast of Taourirt, in eastern Morocco (Van Alstine and Schruben, 1980).

Mozambique—Large vein deposits occur approximately 150 km southeast of Tete. Remote from transportation and from sources of power, this area has been a minor producer of metspar. Further development may result as the area is opened up as a consequence of the construction of the Cabora Bassa dam on the Zambesi River. Six localities are listed by Van Alstine and Schruben (1980).

Nigeria—Deposits containing fluor spar with galena are reported in limestones in the Arufu district of Gongola State near the border with Benue State, in the Benue Trough about 80 km east of Makurdi, and fluor spar in greisens near Jos (Van Alstine and Schruben, 1980).

South Africa—The Republic of South Africa is ranked as third largest fluor spar producing country. Its large reserves indicate it will continue to be prominent in the world picture. Deposits occur in several areas, but production has come principally from mines in the western and northern parts of Transvaal.

Domestically, AECI consumes acid grade to make hydrofluoric acid and the steel industry consumes essentially all of the metgrade as well as about 20 kt/a of 80% CaF_2 briquettes.

The Buffalo open pit mine of Transvaal Mining & Finance, a subsidiary of General Mining and Finance, near Naboomspruit exploits 14 to 16% grade deposits consisting of a network of fluor spar veinlets in sills in a pink granite which is itself an inclusion in coarse Bushveld granite. Similar deposits occur nearby.

Near Warmbad, the Zwartkloof deposit consists of three breccia zones containing a stockwork of fluor spar veinlets in felsite.

At the open pit Vergenoeg mine of Chrome Chemicals, a subsidiary of Bayer, near Pienaarsrivier, fluor spar ore grading 40% occurs with abundant iron oxides (up to 50%) in a massive deposit in felsite.

In the Marico-Zeerust district, fluor spar occurs as replacements in dolomite and as associated residual deposits. Much of the ore in dolomite is disseminated along intersecting fractures. For many years metspar was produced by screening coarse fragments from residual surface deposits. Exploration has disclosed the existence of large reserves of primary ore probably on the order of 54.4 Mt (60 million tons) containing 15 to 30% CaF_2 . Two open pit mines, the Chemspar mine of Phelps Dodge and the Marico mine of Barlow Rand, with capacity of about 120 kt/a, are located here. Armco Bronne, a subsidiary of Armco, Inc., has an active exploration program.

Namibia (South-West Africa)—The Okurusu deposit near Ojiwarongo consists of replacements or segregations in carbonatite and veins in quartzite. After yielding a few thousand tons of metspar, it has been idle. Reserves are indicated to be between 5.4 and 6.4 Mt (6 and 7 million tons) grading 40% CaF_2 . Vein ore near Omaruru was mined open pit and

concentrated to acid grade in 25 kt/a flotation mill from reserves in excess of 272 kt (600,000 tons). Vein and replacement deposits are known in other parts of the country. The lack of water and transportation facilities has hindered development.

Sudan—Fluorspar deposits occur at Jebel Semeih and Jebel Dumbeir approximately 322 km (200 miles) southwest of Khartoum and 1336 km (830 miles) by rail from Port Sudan. At Jebel Semeih a highly siliceous fluorspar vein occurs in a granitic host rock. At Jebel Dumbeir, fluorspar occurs in metasediments as replacements of bands of marble, as thin quartz-fluorite veins, and as bodies of fluorite associated with red feldspathic rock. No production is reported.

Tunisia—A flotation mill at the Hamman Zriba deposit near Zaghuan, 54 km south of Tunis, produces about 30 kt/a of acid grade concentrate from a bedded deposit in Jurassic limestone. Proven reserves are said to be 1.8 Mt (4 million tons) of ore containing 35% CaF_2 and considerable barite. In the same general area, replacement vein deposits occur at Djebel Staa, Hammam Djedida, Djebel Oust, and Djebel el Koho. Other deposits are at Bourchiba, on Cap Bon, and Bou Jaber.

Turkey—Fluorspar deposits in Turkey have been described (Anon., 1965); there is a very small annual production.

Asia: China—China is emerging as a major producer with an annual production of about kt (410,000 tons), mainly from deposits in the central and northern parts of Zhejiang Province, northeastern Hebei Province, northern Guangdong Province, northeastern Anhui Province, and eastern Shandong Province. Other production is at Taoling in Hunan Province, Ming Gang in Henan, at Kaiping in Liaoning Province, and at Yulin in Guangxi Province (a new discovery near rail). In all, fluorspar occurrences are reported in 17 provinces. China exported 95.3 kt (105,020 tons) to Japan in 1978 and 186.4 kt (205,489 tons) in 1979, mainly metallurgical grade.

India—At Amba Dongar, 563 km (350 miles) north of Bombay in Gujarat State, veins and replacement bodies occur in the carbonate wall rock around ankeritic carbonatite intrusives, similar to the occurrences at Okurusu in Namibia (Deans, et al., 1972). Reserves are reported to be 11.6 Mt of 30% fluorite content, of which proven reserves are said to be 4.7 Mt.

Other mineralized areas are reported at Chandri-Dungri in the Drug district of Madhya-Pradesh and at Mando-ki-Pal in the Dungarput district of Rajasthan.

Japan—Japan formerly produced less than 10 kt/a of fluorspar from the island of Hokkaido, but ceased production in 1972 and imports its requirements.

Korea, North—This country has an annual production of about 40 kt.

Korea, South—Fluorspar deposits occur in the northern, central, and southern parts of the country. Approximately 70 mines have been producers, formerly with annual production of about 50 kt, largely for export (Kim, et al., 1972), but production was down to 8 kt in 1979. Both vein and replacement deposits occur. Minable ore reserves have been estimated at 660 kt (Jee and Kye, 1971). Producers have included the Choonchon Shinpo, Dojon, Kumi, Busang, and Kumbo mines.

Pakistan—Minor production has been reported from the Kalat district 72 to 97 km (45 to 60 miles) south of Quetta in Baluchistan. There are also deposits south of Quetta.

Thailand—After the initiation of commercial fluorspar production in 1960, Thailand advanced to the status of one of the largest producers in the world.

Fluorspar deposits occur in a region from the northern border with Burma southward for over 1287 km (800 miles) to a point about 644 km (400 miles) southwest of Bangkok. Active mines are concentrated in three areas: Chiang Mai, Lumpun, and Mai Hongsun Provinces in the north; Kan-chanaburi, Petchaburi, and Ratchaburi Provinces southwest of Bangkok; and Krabi Province in the south (Gardner and Smith, 1965; Anon., 1972; private communication, B. L. Hodge, 1981).

The northern deposits are mainly replacements in Paleozoic limestones which, so far, have been found suitable only for the production of metspar, derived by hand sorting with large resulting waste dumps containing low grade ore. Residual deposits are widespread. In the southern area, the deposits are veins in metamorphosed, fine-grained, fractured Paleozoic clastics and in granite.

Australia: Deposits of fluorspar have been found in all the Australian states except the Northern Territory (Liddy, 1971), but are undeveloped because they are small and remote. There have been investigations in the Chilago-Mungana-Almaden and Forsayth areas of northern Queensland, and in Western Australia in the Pilbara district 217 km (135 miles) southeast of Port Hedland, the Yinnietharra area 322 km (200 miles) from Carnarvon, and the Speewah Valley area southwest of Wyndham.

EXPLORATION

Because fluorspar resists chemical weathering, it can be traced in the soils overlying weathered veins. Cleavage fragments washed clean by rainwater or exposed in anthills or spoil piles from animal burrows are useful clues. Silicified veins resisting erosion may stand up like a "reef." Bedded deposits are less discernable, but in areas of sufficient topographic relief the outcropping edges of deposits or slumped fragments of ore may be found. Owing to its softness and cleavability, fluorspar does not survive in the beds of streams and ordinarily cannot be traced by panning.

The search for bedded deposits usually involves locating a mineralized horizon and following it with vertical drill holes drilled to intersect the favorable beds.

Geophysical prospecting methods are not applicable. Photogeology can be of assistance in locating and tracing structures and outcrops, as well as the areal distribution of stratigraphic units known to be favorable for veins or replacement deposits.

Geochemical methods have been employed with varying degrees of success. Fluorine anomalies have been found in ground waters and surface streams, in soil samples and in stream sediments, but with little practiced success in discovery of ore deposits. Various nonfluorine elements detectable geochemically can be guides to fluorspar deposits.

Once mineralization has been detected, prospect shafts, drifts, and core or churn drill holes are used to probe the structures.

9. Gypsum and Anhydrite*

The two calcium sulfate minerals—gypsum and anhydrite—occur in many parts of the world, and gypsum has long been of economic importance in the family of industrial minerals. Gypsum, the dihydrate form of calcium sulfate ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) and anhydrite, the anhydrous form (CaSO_4) are frequently found in close association, and it is seldom that a calcium sulfate deposit will consist exclusively of one mineral or the other.

Although known gypsum deposits are extensive, anhydrite makes up the largest part of total calcium sulfate reserves. However, it has very minor economic use, and most of the following discussion will be devoted to gypsum.

Calcium sulfate is one of the principal constituents of evaporite deposits, and when pure, has the following composition:

	Lime, CaO, %	Sulfur Trioxide, SO ₃ , %	Combined Water H ₂ O, %
Gypsum	32.6	46.5	20.9
Anhydrite	41.2	58.8	—

Deposits of pure gypsum or of pure anhydrite which are large enough to be considered commercial have never been found because of both the metastable relationship between the two minerals and the presence of impurities such as calcium or magnesium carbonates, chlorides, other sulfate minerals, clay minerals, or silica. As a result most mine production of gypsum will range between 85 and 95% pure. Often it is used as mined, although in certain cases, one or more forms of mineral beneficiation are employed to upgrade the product.

END USES

The largest use for gypsum is based upon the unique property which calcium sulfate has of readily giving up, or taking on, water of crystallization. With the application of a moderate amount of heat in a process known as calcining, gypsum is converted to plaster of paris (the hemihydrate of calcium sulfate, $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$) which, when mixed with water, will set or harden as the calcium sulfate returns to the dihydrate form. This semifinished product, usually called stucco, is then manufactured into a large variety of plasters, wallboard, and block for construction use, or into plasters for industrial applications. About 75% of the gypsum used in the United States is calcined for these purposes.

Uncalcined uses of gypsum are principally as a retarder for portland cement, as a soil conditioner, as a mineral filler, and other minor industrial applications. About 25% of the gypsum mined in the United States goes into these markets; however, in less developed countries where construction and other industrial uses may be quite limited, the use of uncalcined gypsum for portland cement retarder may well be the dominant—if not the only—market for the mineral.

It has often been noted that calcium sulfate constitutes

the world's largest reserve of sulfur, and minor use of both anhydrite and gypsum has been made to produce sulfuric acid or other sulfur compounds such as ammonium sulfate. However, because sulfur is readily available at lower cost from other sources, use of calcium sulfate has been limited to only a few locations where it could compete economically. No such use is reported in the United States at this time.

MINERALOGY

Anhydrite, CaSO_4 , because of its geologically rapid conversion to gypsum, and relatively high solubility (about 0.2 g/100 g H_2O) is not often found outcropping in climates wet enough to support abundant vegetation except on steeply dipping slopes or other places where hydrated material is continuously removed. Anhydrite rock is most often light to bluish gray in color and under the microscope varies from granoblastic (ver Planck, 1952) to feltylath crystal aggregates.

Bassanite, $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$, is a distinct phase intermediate between anhydrite and gypsum, but is identifiable only by X-ray diffraction or petrographic techniques using very carefully prepared samples. Bassanite is metastable under ordinary conditions (Wood and Wolfe, 1969); however, its occurrence in amounts under 1% is suspected to be widespread in calcium sulfate mineral deposits.

Gypsum, $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$, is the commonly observed calcium sulfate mineral in rock outcrops because of its diverse origins. It is easily distinguished from anhydrite by its inferior hardness (2.0 vs. 3 to 3.5) and lower specific gravity (2.2 to 2.4 vs. 2.7 to 3.0 for anhydrite). Most gypsum is white to grayish white although the impurities in any given deposit frequently determine the color of the rock and resulting products. Petrographically, most rock gypsum is granoblastic (Goodman et al., 1957). Commercial deposits show a great variety of crystal sizes and textures, both from deposit to deposit and within a single deposit. Relatively undisturbed deposits often contain texturally consistent stratigraphic units, but, in deposits that have been deformed, the gypsum is often recrystallized and shows a variety of textures. Many deposits exhibit porphyroblastic textures wherein two distinct sizes and ages of crystals occur (Holiday, 1970), and in some deposits fibrous gypsum similar to felty-lath anhydrite makes up the mass (Van't Hoff, et al., 1903).

Alabaster is a compact, very fine grained variety of rock gypsum prized by sculptors for its uniform workability under the chisel, and occasionally is found within commercial deposits. Fibrous gypsum composed of needle-shaped crystals in orientation parallel to the C-axis (Schmidt, 1914), is known as **satin spar** and is a type of stress mineral indicative of deformation. It is universally a secondary mineral and occurs widely as a fracture filling wherein the needle lengths are perpendicular to the fracture walls and less commonly in shear zones wherein the needles are parallel to the direction of movement. Large euhedral gypsum crystals and large cleavages commonly known as **selenite** form in fluid-filled spaces or in an easily deformable host material, and are sometimes mistakenly identified as mica by the uninitiated. Both satin spar and selenite are of little or no economic importance other than being accessories in rock gypsum, although one deposit consisting primarily of coarse selenite crystals is being worked near Apex, NV (Bergstrom, 1961).

*Excerpt from Appleyard, F.C., "Gypsum and Anhydrite," *Industrial Minerals and Rocks*, 5th ed., Vol. 2, S.J. Lefond, ed., AIME, New York., pp. 775-792.

ORIGIN AND OCCURRENCE

The calcium sulfate minerals are deposited by precipitation from aqueous solution when the concentration of the components and the physical conditions are suitable, with the majority of the deposits originating from evaporation and concentration of marine brines in a dry climate, i.e., evaporite conditions. That this is the basic mechanism of formation of economic calcium sulfate deposits is unquestioned; however, there is considerable discussion in the literature as to the physical environment in which precipitation takes place, and as to whether the originally precipitated mineral is gypsum or anhydrite.

The older, well established concept of deposit formation idealizes a brine-filled basin having restricted circulation (Branson, 1915; King, 1971), which permits limited replenishment of the brine as it evaporates. The resulting concentration causes precipitation of the contained salts in the inverse order of their solubility, and substantial thickness of essentially monomineralic deposits (e.g., calcium sulfate) are visualized as being derived from this type regime, an example of which is the A subzone of the Mississippian Windsor series of southeastern Canada.

A more recent concept of evaporite deposition has resulted from considerable work done in the Trucial Coast of Arabia (Butler, 1970; Kinsman, 1966, 1969) which describes the *sabkha* supratidal environment wherein calcium sulfate minerals are currently being deposited (*sabkha*, an Arabic word denoting salt-flat—Kinsman, 1966). These deposits are characterized by a distinctive sequence of sediments including lagoonal limestones, intertidal algal mat limestones, and precipitation of gypsum crystals and nodular anhydrite in the preexisting host sediments, which, if originally calcium carbonate, become dolomitized. Clastic sediments, if present, are unaffected chemically, but are contorted and displaced as the gypsum crystals and nodular anhydrite grow in them. In the *sabkha* regime, a basin is not required for deposition, although some concentration of the original seawater brine does take place in along-shore lagoons. Thick chloride accumulations would not be expected (Schroeder, 1970). The Mississippian evaporates of southwestern Indiana illustrate this type of deposit (Jorgensen and Carr, 1972).

The classical in-basin accumulations of sulfates and chlorides might be expected to have *sabkha* deposits along the margin of the basin, and the Silurian gypsum of Ohio, Ontario, and New York is possibly of this origin. The individual sulfate beds in *sabkhas* do not commonly exceed 6 to 12 m (20 to 40 ft) in thickness, although 61-m (200-ft) accumulations have been described in Jamaica, WI (Holliday, 1971).

Gypsum may also precipitate along fractures, bedding planes, or in other available spaces where ground water carrying sulfate ions from the oxidation of sulfides comes into contact with carbonate rocks. Such deposits, however, are of limited extent, and rarely—if ever—could be expected to have economic importance.

Because gypsum will precipitate wherever brine concentration is appropriate, and recrystallizes or dissolves readily as the metastable or temporary environments change, interpretation of geologic evidence to determine exact depositional environments is difficult at best. Several works (Dean and Schreiber, 1978; Kendall, 1978; and others) are helpful in determining depositional environments.

Gypsite deposits usually occur in semiarid and arid climates, and result from the solution of existing gypsum deposits by ground water, which in turn is drawn toward the surface by capillary action where it evaporates to deposit the

dissolved sulfate as a porous aggregate of gypsum containing considerable impurities. Also, in a few cases, reworking of existing deposits by wind erosion has concentrated gypsum in sand deposits, as at White Sands, NM, or Cuatrocienegas, Coahuila, Mexico.

Of totally different origin are those calcium sulfate deposits which constitute part of the cap rock of salt domes in the Gulf Coast basin. The exact origin of these domes is not fully understood but most prevailing views involve flowage and upward movement of plastically deformed salt in response to overburden pressure from the overlying sediments (Martinez, 1974). Once the upward movement is initiated, it is possible for the top of the lighter salt mass to be injected into and through the overlying sediments.

The theory most widely accepted as to the origin of the cap rock is that it represents a residue of anhydrite and other relatively insoluble minerals which accumulate at the upper surface of the salt dome as it rises through water-bearing sediments and the salt is dissolved. The anhydrite crystals, which make up about 99% of the water-insoluble residue (Walker, 1974), are then recrystallized and compacted to form a massive rock which may be locally hydrated to form gypsum.

The total height of a salt dome can exceed 3048 m (10,000 ft), with the cap rock being well over 305 m (1000 ft). Most domes are roughly circular in plan view, and range in diameter from about 1000 m (3280 ft) to more than 6.4 km (4 miles) although there is great diversity in dome geometry and dome-to-cap-rock relationships. Most domes do not reach the present surface, although occasionally cap rock is found at or near the surface and might be of economic significance.

DISTRIBUTION OF DEPOSITS

Calcium sulfate minerals have been found within every geologic system from Silurian through Quaternary. The largest production in North America is from Mississippian rocks in southeastern Canada, Michigan, Indiana, and Virginia, followed by that from Permian rocks in Texas, Oklahoma, Kansas, Colorado, Wyoming, Nevada, and Arizona. Production from Tertiary rocks is obtained in California, Jamaica, and Arizona, from Jurassic rocks in Iowa, New Mexico, Colorado, Utah, Wyoming, and Montana, and from Silurian rocks in New York, Ontario, and Ohio. Elsewhere, Tertiary rocks in Australia, France, and Italy, Permian and Jurassic rocks in England, and the Triassic in France, Germany, and England contain large commercial deposits. Commercial deposits range in thickness from 101 cm (40 in.) to over 31 m (100 ft), and reserves of individual deposits are usually measured in millions of tons. Production rates commonly average 181 to 272 kt/a (200,000 to 300,000 tpy) from each operation, but range from a few thousand tons up to about two million tons.

Although gypsum is produced from rocks of many ages, many deposits are Quaternary in age due to the recent and continuing conversion of anhydrite to gypsum that occurs under certain conditions. This conversion of anhydrite to gypsum, as well as the reverse reaction, has been extensively studied because of its importance in the original sequence of deposition from brines, as well as in metamorphism that occurs in calcium sulfate deposits after deposition. Several reviews have been made (Braitsch, 1971; Hardie, 1967; MacDonald, 1953; Wood and Wolfe, 1969) of such variables as brine composition, temperature, water pressure, and overburden pressure. From these, it is evident that no one set of conditions applies to all deposits. On the contrary, all

these variables, plus structural, lithological, and topographical considerations, which might affect water migration, must be examined in order to understand the degree of hydration of any given calcium sulfate deposit. To date, however, only limited attempts have been carried out in an effort to integrate theoretical models with field evidence of rock textures and structures.

Most commercial gypsum deposits are believed to have resulted from the action of surface and ground waters upon anhydrite, and hydration has been found at depths ranging from zero to more than 610 m (2000 ft) below the surface. In many deposits, the degree of hydration is readily predictable once the variables controlling it are understood; however, in others the degree of hydration can vary widely, with corresponding reduction in the amount of available reserves, and increase in the cost of mining. In all cases, the operator is well advised to thoroughly explore and understand the anhydrite-gypsum relationship prior to development of a mine.

Impurities in Calcium Sulfate Deposits

The number of minerals which can occur in evaporite deposits is quite large (Braitsch, 1971), and many can be found as impurities in calcium sulfate deposits. Their occurrence is often dependent upon the mode of formation of the deposit. In varying degrees, most gypsum and anhydrite deposits contain clastic sediments, commonly clay minerals and fine sands, as well as chemical sediments such as limestones and dolomites. In sabkha-type deposits, these preexisting sediments will fill intermodular spaces of the gypsum and anhydrite or form crude layers, and often appear to be replaced when they actually are displaced. Relatively insoluble evaporite minerals such as celestite, certain borates, some carbonate minerals, and silica may occur in calcium sulfate deposits as discrete crystals, crystal aggregates or nodules, and probably are in many cases original depositional features. However, strontium or boron, which may present in only trace amounts in anhydrite, may migrate during gypsification to result in strontium and boron mineral accumulations.

Soluble evaporite minerals, e.g., halite, sylvite, mirabilite, epsomite, and others are also frequently found in calcium sulfate deposits. These too are expelled from anhydrite during gypsification, and most commonly become associated with the clay minerals that may be present, probably being adsorbed on the clay mineral surfaces. They also are associated with the carbonate impurities where they may be absorbed into mineral surfaces, held as fluid inclusions, or included in a disordered lattice. In addition, these soluble minerals can occur as microfracture filling. The hydration halo of mixed gypsum-anhydrite commonly contains many times the soluble salt content of either unhydrated anhydrite or hydrated gypsum. Individual deposits show great variation in the quantity and type of soluble salts present, i.e., sulfates or chlorides, and it has been noted that, in general, chloride salts predominate in gypsum deposits of eastern North America, whereas sulfate salts exceed chlorides in western North American deposits.

In addition to the foregoing, evaporite mineral impurities whose origin is generally a feature of original calcium sulfate deposition, in any given mining operation may also be encountered as a result of structural features such as tight folding or faulting, or from recent erosional activity. These usually take the form of clays, sands, or gravels and occur most often in near surface deposits, although structural deformation can result in severe impurity problems at consid-

erable depth. More often than not, the greatest quantity of impurity in a gypsum deposit is anhydrite (and vice versa), a result of the metastable relationship of these two minerals, as previously discussed.

As utilized, most gypsum contains from 10 to 15% of impurities, although some deposits may be exceptionally pure (i.e., plus 95%) or somewhat impure (i.e., 80%). In general, the amount of impurity which can be tolerated depends upon: (1) the type of impurity, (2) the product being manufactured, and (3) the competitive situation.

Based upon the effect impurities may have upon the manufacturing process and finished products, impurities may be separated into three categories:

- 1) Insoluble or relatively insoluble minerals such as limestone, dolomite, anhydrite, anhydrous clays, silica minerals, etc.
- 2) Soluble chloride minerals such as halite, sylvite, etc.
- 3) Hydrous minerals such as the sulfate salts mirabilite and epsomite and the montmorillonite group of clays.

The first category, to the extent that the minerals replace gypsum, reduces the strength of rehydrated stucco and increases weights of the finished plaster or wallboard, i.e., more pounds of an impure stucco are required to obtain a given strength. Nevertheless many commercial gypsum deposits contain as much as 10 to 15% of these insoluble impurities. The presence of the second category, soluble chloride salts, affects calcining temperature and stucco slurry consistency and set time. These impurities are usually limited to no more than 0.02 to 0.03%. The principal impact of the third category is in moisture pickup of the finished product and on bonding characteristics of the gypsum stucco core of wallboard to its paper covering. Hydrous sulfate salts must be limited to 0.02 to 0.03% (too much causes the paper to peel off wallboard); however, hydrous clays up to 1.0 to 2.0% may be tolerated.

MAJOR NORTH AMERICAN PRODUCING AREAS

The principal gypsum producing areas in North America are shown in Fig. 1. In addition, there are many more known, but undeveloped gypsum deposits, especially in the mid-western and western states, southeastern Canada, and Mexico. Domestic reserves are geographically distributed in 23 states and have been estimated to contain 18.1 Gt (20 billion tons) or approximately 2000 years' supply at current production rates (Schroeder, 1970). Quantitative information is lacking on gypsum reserves in the rest of the world, but deposits are widespread, and inferred reserves are considered to be unlimited in relationship to requirements.

A brief description of the major North American producing districts follows.

Southeastern Canada

Marine evaporates of Mississippian (Visean) age underlie much of southern New Brunswick, northern Nova Scotia, and southwestern Newfoundland. The first production of gypsum in North America was recorded in Nova Scotia about 1735 and has grown to make this the largest gypsum mining region in the world, with an annual production exceeding 5.4 Mt (6 million tons).

Calcium sulfate is found in, or is correlative with, the Windsor Group which has been divided into five subzones: A, B, C, D, and E in ascending order. Although calcium sulfate is present in each of these subzones, the economic deposits of gypsum and anhydrite are confined to the Lower Windsor, i.e., subzones A and B. The most extensive is the A subzone, consisting of up to 305 m (1000 ft) of anhydrite

Fig. 1. Location of North American gypsum-producing districts.

with occasional thin dolomite beds. Where topographic conditions are favorable, surface hydration, which rarely exceeds 9 to 12 m (30 to 40 ft), has produced several deposits of dense, white, high purity gypsum.

The B subzone, which varies in thickness from 76 to 152 m (250 to 500 ft) consists of interbedded calcium sulfate, limestones, and siltstones. The calcium sulfate, representing about 80% of the section, has been hydrated to depths varying from 46 to 213 m (150 to 700 ft), although occasional remnant anhydrite lenses with associated soluble salts are encountered. Unlike most gypsum deposits which have only minor structural features, if any, the rocks of the B subzone are frequently deformed by complex plastic folding and by occasional faults of substantial displacement, which make for difficult mining conditions. Nevertheless, the B subzone accounts for approximately 75% of the region's total production.

The southeastern Canada gypsum deposits are usually covered by glacial till which may be as thick as 61 m (200 ft), but averages 12 to 15 m (40 to 50 ft). All mining is by open pit methods.

Iowa

The largest single gypsum producing district in the United States is at Fort Dodge, IA, where mining began in 1872. Long considered to be an outlier of the Permian Basin, this deposit is now thought to be Jurassic in age (Cross, 1966). It consists of a single bed of gypsum up to a maximum of 9 m (30 ft) in thickness, but which probably averages nearer 3.7 to 4.3 m (12 to 14 ft). Its areal extent of some 39 km² (15 square miles) appears to be limited by post-depositional erosion, particularly during the period between

Late Cretaceous and the Pleistocene. Its continuity is interrupted by wide channels apparently formed prior to and/or during the glacial period, channels which cut through the gypsum into the underlying shales.

Overburden consisting of glacial till, varies from 6 to 18 m (20 to 60 ft), and the rock surface is commonly cut with mud-filled erosion crevices which must be cleaned out, thereby posing a mining problem; however, gypsum purity as used is usually plus 90%. Mining is by open pit methods, with four companies operating in the district.

Michigan

Another important gypsum source in the midwest is the Michigan Basin, with two producing districts: Grand Rapids in the southwestern portion of the basin, and Alabaster-National City near the northeasterly edge on Lake Huron. These deposits are in the Michigan formation of Mississippian age, and consist of multiple units of gypsum (5 to 40 ft) thick, separated by beds of shale varying from a few meters (feet) to 12 to 15 m (40 or 50 ft) thick.

Three operations are active in the Alabaster-National City area, using open pit mining methods to recover three gypsum beds [separated by 1.5 m (5 ft) of shale] at Alabaster, and a single bed at National City and Turner. Overburden is glacial till ranging in thickness from 12 to 21 m (40 to 70 ft), and at Alabaster, where the gypsum grades into anhydrite as the overburden thickness increases, a minor amount of anhydrite is also produced.

New York—Ontario

Gypsum is found in a belt of Upper Silurian rocks which extends eastward from the Niagara Peninsula in Ontario across New York to the vicinity of Utica. The first recorded mining of gypsum in the United States took place in this belt in 1808 near Syracuse. In recent years, however, all production has come from the Oakfield area near Buffalo in the western part of the state, where one operation currently is active. The economic gypsum here consists of a 91-122-cm (36-48-in.) thick bed in the Salina Group of Upper Silurian age, overlain by 3 to 12 m (10 to 40 ft) of thinly bedded shales and dolomites, covered by glacial till ranging up to 15 m (50 ft) in thickness.

Ohio

On the shores of Sandusky Bay of northern Ohio, gypsum has been continuously mined since 1849, with one open-pit mine being currently active. Several beds of calcium sulfate are found in the Tymochtee formation of Upper Silurian age, all of which are relatively impure due principally to inclusion of dolomite stringers and nodules and, to a lesser degree, anhydrite. As mined, this gypsum is probably the lowest grade of any commercial deposit in the United States (with the exception of gypsite in California) being in the 65 to 70% range; however, mine production is benefited by heavy media sink-float to produce an approximately 80 to 81% gypsum product.

Indiana

In 1952, gypsum was discovered in southern Indiana near the town of Shoals, and this has become one of the most important commercial gypsum producing districts in the United States. In part of the Illinois Basin, gypsum occurs in the St. Louis formation of Mississippian age, and lies 107 to 168 m (350 to 550 ft) below the surface of this rather hilly area. The bed averages 4.3 to 4.9 m (14 to 16 ft) thick.

The St. Louis limestones overlying the gypsum have been subjected to solution along bedding and joint planes to create

a network of water-filled cavities of undetermined extent and location.

Virginia

In the western tip of Virginia near Saltville, gypsum has been produced continuously since 1835, first from shallow pits or quarries and currently from one underground mine.

The calcium sulfate originated in the McCready formation of Mississippian age, but the deposits are structurally very complex as a result of Appalachian mountain building, and in particular, the Saltville fault, a major northeast-southwest trending thrust fault which in the Plasterco area has a vertical displacement of over 4.3 km (14,000 ft). As mined, the calcium sulfate is found in part as a more or less continuous bed, approximately vertical and varying in width from 2 to 3 m (8 to 10 ft) up to 6 m (20 ft); and in part as remnants or fragments of an originally horizontal bed (or beds) known locally as "boulders."

Hydration of the calcium sulfate is highly irregular and, as with most deposits, is a function of the availability of ground waters. As a general trend, there is less hydration at depth than near the surface; however, the ultimate limit of sufficient hydration to support a viable operation is as yet unknown.

Permian Basin

One of the major geological features of the United States is the Permian Basin extending over parts of Texas, New Mexico, Oklahoma, and Kansas, and calcium sulfate is found extensively over this area. Where hydration has occurred, the resulting gypsum is usually of high (plus 92%) purity and, in fact, most of the specialty gypsum products which require high quality raw material are made from deposits of Permian age. The best purity and whitest color gypsum being commercially exploited in the United States is found in the Blaine formation of the Permian at Medicine Lodge, KS, and Southard, OK, and in the Easy Creek formation of the Permian at Blue Rapids, KS.

At the present time, there are seven operating mines in Texas, six in Oklahoma, and two in Kansas. All of the Texas and Oklahoma deposits are worked by open pit methods, but the two Kansas mines are underground.

Although considerable Permian calcium sulfate is found in southeastern New Mexico, none currently is being mined. There are, however, two operating mines (open pit) in the north-central part of the state working gypsum of the Todilto formation of Jurassic age.

Rocky Mountain and Intermountain States

This general area is particularly rich in calcium sulfate deposits, most of which are at, or just below, the surface and lend themselves to low cost open pit mining. As might be expected in this region, structural features play an important part in limiting the size of the deposits and in mine design. In general, purity is good, but the extent of hydration is frequently difficult to predict. A major deterrent to development is the cost of transportation due in part to the distance to roads and railroads, and, also, the long hauls to major markets.

Gypsum is currently produced in the Powder River Basin area of Wyoming from rocks of Upper Permian to Middle Jurassic age, and from the Front Range of Colorado in Larimer and Fremont Counties. Production has also been developed in Fergus County, MT (Piper formation, Jurassic age) and Sevier County, Utah (Arapien shale, Jurassic age).

In Nevada, two deposits are mined in Clark County and one in Pershing County, with most of the product from these

operations being shipped to California markets. In Arizona, a deposit at Winkelman provides gypsum for a calcining and manufacturing operation in Phoenix, and three smaller operations in the state supply portland cement retarder and agricultural markets. All of these western operations are open pit mines with the exception of Montana.

California

Gypsum rock for five of the seven calcining and manufacturing plants in California is shipped into the state from Mexico (four plants) and Nevada (one plant). The other two utilize gypsum from a deposit in Imperial County, which in 1979 produced approximately 816 Mt (900,000 tons), making it the largest operating gypsum mine in the United States. This deposit, of Miocene age, occurs as a remnant of a calcium sulfate bed well over 30.5 m (100 ft) thick whose present extent is limited by structure and erosion. Nevertheless, it contains large reserves, in part because hydration has taken place to a greater degree than in many other cases. Little or no overburden is present, and mining is carried out by multi-bench open pit methods (ver Plank, 1952).

For many years, several low grade gypsite deposits have been worked in San Joaquin Valley to produce a 50 to 75% gypsum content material for use as a soil conditioner. These deposits are Holocene in occurrence and are of limited extent. Although of too low a purity for portland cement retarder or plaster products, they are important in treating the alkaline soils which predominate in the great agricultural valleys of the state.

Western Canada

Gypsum is produced from two open-pit mines, one in Manitoba, the other in British Columbia. These operations provide rock for eight calcining and manufacturing plants in the western provinces. Also, one plant in Vancouver is supplied with rock imported from Mexico.

Production from these deposits is used almost entirely in the manufacture of building products and as a portland cement retarder. In both cases, only mining and primary crushing operations are carried on at the mine site, with the crushed gypsum rock being shipped to plants located in or near the major cities of Winnipeg, Saskatoon, Calgary, Edmonton, and Vancouver.

Mexico

The primary use for gypsum in Mexico is as a retarder for portland cement and for building plaster, although in 1971 two small wallboard plants began operation in the city of Puebla in an attempt to introduce wallboard to the construction markets. Considerable gypsum is also exported to the West and Gulf Coasts of the United States, and on occasion, to the Far East.

Many large deposits are known to exist; however, at the present time the major producers are located on San Marcos Island in the Gulf of Baja California and in the states of Puebla, San Luis Potosí, and Nuevo Leon. In general, the gypsum is found in rocks of Mesozoic and Tertiary age.

The largest volume of production in Mexico is from San Marcos Island where an open pit mine and deep water ship loading facilities are operated to produce and ship a crushed gypsum rock. Another large highly mechanized open pit mine is operated at Estación La Borreguita in the state of San Luis Potosí to produce a crushed gypsum which is shipped by rail to local cement companies and to the port of Tampico for export.

In the state of Puebla, from the town of Izucar de Matamoros on the east to the village of Axochiapan on the west,

a zone of gypsum bearing rocks of Miocene-Pliocene age occurs in which several small quarries are operated. These provide gypsum for some eight or nine cement plants in the Mexico City-Puebla area, for two new gypsum board plants at Puebla, and for several small calcining operations making gypsum plaster. The highest purity gypsum presently mined in Mexico comes from near Monterrey, Nuevo Leon, where at least two calcining plants operate to produce plaster for both construction and industrial uses.

Caribbean Area

Two deposits are being worked in the Caribbean Area: one at Bull Bay, Jamaica, about 16 km (10 miles) east of the capital of Kingston; and the other near Barahona, Dominican Republic, some 209 km (130 miles) west of the capital city of Santo Domingo. In both countries only small domestic gypsum markets have been developed primarily for portland cement retarder, and the major part of the production serves the export trade.

In Jamaica calcium sulfate is of Lower Eocene age, and occurs as several separate bodies of relatively small size in a northwest-southeast trending basin known as the Wag-water Trough (Holliday, 1971). Perhaps 60 to 70% of the calcium sulfate mass has been hydrated, and gypsum is currently being mined from three different deposits, utilizing multibench open pit methods.

The Dominican Republic gypsum is of probable Upper Miocene age, and the largest outcrop is found in the Cerro de Sal, a 19-km (12-mile) long hogback trending northwest-southeast. Calcium sulfate is interbedded with limestones, claystones, sandstones, and salt of the Cerro de Sal formation with a total thickness of some 610 to 762 m (2000 to 2500 ft). Bentonite clays and soluble salts are a potential problem associated with some stratigraphic members. The geological structure has been complicated due to several repetitions of the stratigraphic column caused by faulting; however, large deposits of economic gypsum may exist. Mining is by open pit methods. At least three other gypsum outcrops are known in this general area, but to date have not been developed for production.

GYPSUM RESOURCES OUTSIDE NORTH AMERICA

Reflecting its wide geologic occurrence and its basic use in the construction industry, gypsum is produced in some 72 countries around the world. No statistics are available as to the potential world reserves of calcium sulfate, but it can be safely predicted that they are enormous both in terms of total tons and of years at the present rates of consumption.

In many of the countries reporting production, gypsum was used only for portland cement retarder, this being by far the most common use of the mineral on a worldwide basis. As a general rule, the calcining of gypsum for use as plaster and wallboard building materials, or for industrial plasters, is limited to the United States, Canada, Europe (including Russia), and Japan, although a few wallboard plants have recently been built or are being considered in certain South American and Asian countries. In these countries, the general practice of open structural frames, usually made of wood, to form a building has historically required the use of some type of covering material for walls and ceilings, and gypsum products have gained wide acceptance for this use. That is, gypsum in the form of either plaster or precast wallboard is a versatile, fireproof covering material, and these products account for over two-thirds of the gypsum used in the United States and Canada.

Conversely, in those countries where the usual methods of construction rely heavily on masonry products, such as concrete, concrete block, stone, and brick (including adobe), the need for fireproof covering materials is much less, and the use of gypsum for the manufacture of building materials will be very small, or even nonexistent. The production and use of gypsum in a given country, therefore, is usually a result of its mode of use rather than the availability of gypsum deposits.

EXPLORATION METHODS

As for most minerals, a thorough understanding of the origin and occurrence of gypsum is essential before undertaking an exploration program. This may be obtained by a review of published literature, and a basic reference would be "Selected Annotated Bibliography of Gypsum and Anhydrite in the United States and Puerto Rico" by C.F. Withington and M.C. Jaster (1960).

By studying the stratigraphic column in regions where sedimentary rocks occur, an indication can usually be obtained from the lithology whether or not an evaporite environment may have existed, this being, of course, a requisite for the deposition of calcium sulfate. If evaporite rocks are indicated, further details can be obtained from examination of outcrops of the particular formations or, if outcrops are not available, from logs of oil or gas wells or from water wells which may have been drilled in the vicinity. Perhaps drill cuttings, or even core, might be available for inspection. As stratigraphic and lithologic details of an area are thus developed, structure should also be mapped so as to provide as detailed a picture of the area as the basic data will permit. From this, the possibility of calcium sulfate occurrence usually can be predicted and, also, it may be possible to judge the potential for hydration of the sulfate zones.

Sources of this type of information are published literature, unpublished university theses, geological surveys, geological departments of colleges and universities, oil companies, and water well drillers.

Geophysical work is only partially applicable to the search for calcium sulfate. The right combination of logs may indicate gypsum or anhydrite, but no log has yet been devised that will replace accurately a laboratory chemical or purity analysis. Geophysical logs are useful for determining structural details and can be used, in conjunction with other tests, to help determine mining environment conditions. Geochemical methods are rarely applicable to calcium sulfate, although heavy concentrations of sulfate in ground waters might serve as a useful clue, and in a few instances differences in plant species may indicate changes in rock types that can aid in surface mapping.

Even though the extent of gypsum can be mapped from surface outcrops, drilling is necessary to predict the amount and regularity of hydration, i.e., how much of the calcium sulfate is gypsum, and how much is either only partially hydrated or is anhydrite. For deeper deposits, additional drilling data is almost always required to map projections of lithologies and/or structures. Core drilling is usually preferred, taking BX (or larger) size core to provide adequate material for sampling and to permit good core recovery. In some cases where it is only necessary to determine the depth of overburden, or to locate the contact between gypsum and anhydrite, rotary drilling is sufficient and is much less expensive. Also geophysical methods can be successfully used under some conditions to determine the depth of overburden.

Although calcium sulfate beds may sometimes be continuous over tens—or even hundreds—of miles, the explo-

ration geologist should keep in mind that they may also occur as discontinuous lenses. Also the extent of hydration is even less predictable, as is the occurrence of minor, but detrimental, amounts of impurities. Hence a successful exploration program requires knowledgeable consideration and interpretation of all the factors involved, and sums of money which can run into six figures.

10. Kyanite and Related Minerals*

INTRODUCTION

The sillimanite family of minerals, including kyanite, sillimanite, and andalusite, are anhydrous aluminum silicates with the formula $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$. Dumortierite and topaz are also included in this group because they are closely allied in composition and thermal behavior. However, neither are mined commercially today. They are typical metamorphic minerals which are found in metamorphic rocks on every continent. Sillimanite minerals are prized chiefly for their refractoriness and are important components in a broad range of acid refractory products, especially in mortars and castables. While these minerals have widespread occurrence, the consumption of sillimanite minerals is concentrated in the relatively few highly industrialized areas where refractories are manufactured, and which in turn are typically close to the major iron and steel producing regions of the world. Thus northern Europe, England, the United States, and Japan are the principal consumers of refractories and sillimanite minerals. Of these countries, only the US is a significant producer.

Kyanite

The largest use for domestic kyanite, both raw and calcined, is in the manufacture of refractory mortars, cements, castables, and plastic ramming mixes. In these applications kyanite constitutes from 10 to 40% of the mixture, the balance being refractory clays and coarser grog materials. A certain proportion of raw kyanite is used to offset the shrinking of the clay binder, whereas the calcined kyanite is used in the coarser sizes for body.

Sillimanite

Granular and massive forms of sillimanite are used in much the same way as granular and massive kyanite. Massive sillimanite from India and South Africa has been used for sawed block refractories principally in the glass industry in Europe. The massive varieties of kyanite and sillimanite have not enjoyed much use in the United States in recent years, but have been widely used by European refractory producers. Conversely, until recently, little granular domestic kyanite had found much application outside of North America. The use pattern is changing as a result of the depletion of the high grade massive deposits of the world, and of the increasing production of kyanite, andalusite, and sillimanite concentrates in India and Africa from deposits formerly thought to be unworkable. Andalusite concentrations are now being produced in France and are displacing or augmenting aluminum silicate sources from abroad.

The potential use of kyanite, sillimanite, and andalusite for the production of aluminum-silicon alloys has been investigated. To be an economic possibility, however, it appears that it would be necessary to produce aluminum silicate concentrates considerably purer than those currently produced and at a cost about half what the present market will bear. Short of some unforeseen and dire circumstances cutting off the free world trading and marketing of bauxite and silica, the likelihood of such production seems remote.

GEOLOGY

Mineralogy

The properties of the kyanite group of minerals are given in Table 1.

Classification of Deposits

Kyanite: Kyanite Quartzite—The kyanite produced in the United States comes from kyanite quartzites. Kyanite quartzites are rocks containing 15 to 40% kyanite and usually about 5% of other minerals such as pyrite, lazulite, rutile, and mica. The rock is characterized by an anomalously low content of potash and soda and the virtual absence of calcium and magnesium. The alumina content of kyanite quartzite ranges between 10 and 25% and averages about 18% Al_2O_3 , which is generally similar to that of the schistose rocks which enclose the kyanite-bearing strata.

Kyanite quartzite deposits occur in the Piedmont region of the Appalachian Mountain system in a relatively narrow zone extending from northeastern Georgia through central South and North Carolina to southeastern Virginia. They are enclosed within a wider band of mildly metamorphosed acid metavolcanics and sediments known as the Volcanic Slate Belt in Virginia and the Little River Series in Georgia. The age of the rocks is uncertain, but several workers have suggested that they are lower Cambrian in age (Bennett, 1961).

More recent studies by Carpenter and Allard (1980) expand the mineralization and alteration theories of kyanite in the Georgia-South Carolina-McCormick district.

There are at least 13 distinct deposits of kyanite quartzite within this zone. All of them are known as "mountains" owing to their solitary prominence rather than their relatively modest height. Graves Mountain in Georgia, and Willis Mountain, Baker Mountain, and East Ridge all in Virginia are being mined at the present time. Until 1970, the Henry's Knob deposit in South Carolina was also mined (Espenshade and Potter, 1960).

In southeastern California and extending into southwestern Arizona there is a zone of metavolcanics whose composition and lithology resembles that of the Carolina Slate Belt in which kyanite quartzite deposits are also found. However, the kyanite in these deposits, while averaging 25 to 35% of the rock in apparently large and recoverable crystals, has proven to be contaminated with extremely fine inclusions of quartz. To date, it has not been possible to produce a competitive kyanite product from these western kyanite quartzite deposits.

Kyanite quartzite has been described in several places in the world, and usually seems to occur within a geologic framework similar to that of the deposits of the southeastern United States. Such deposits have been described and explored in Surinam, Norway, Kenya, and Austria (Varley, 1968).

Kyanite Schist and Gneisses—Kyanite is very common in the highly metamorphosed schists and gneisses of the metamorphic regions of the world. Typically, the kyanite occurs in quantities ranging from a percent or two to as much as 25% in a gangue of biotite, feldspar, muscovite, garnet, and occasionally hornblende and other common rock forming minerals. Rocks containing a few percent of kyanite are extremely abundant and widespread. They are exposed over hundreds of square miles in the eastern and western

*Excerpt from Bennett, P.J., and Castle, J.E., 1983, "Kyanite and Related Minerals," *Industrial Minerals and Rocks*, 5th ed., Vol. 2, S.J. Lefond, ed., AIME, New York, pp. 799-807.

Table 1. Properties of Kyanite Group Minerals

	Andalusite	Kyanite	Sillimanite	Mullite
Formula	$\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$	$\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$	$\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$	$3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$
Crystal system	Orthorhombic	Triclinic	Orthorhombic	Orthorhombic
Cleavage	{110} good {100} poor	{100} perf. {010} good {001} parting	{010} good	{010} perf.
Hardness	6–5–7	5.5–7*	6.5–7.5	6–7

*Varies with direction.

metamorphic areas of North America and in the metamorphic rocks of other continents.

Repeated attempts to recover the kyanite from such rocks have been made. The most recent attempt was in the Timiskaming district in western Quebec by North American Refractories Co. of Cleveland, OH. An earlier effort was made in the late 1930s near Burnsville, NC. At the present time no kyanite schists are being mined for kyanite.

In order for such kyanite to be economic it is necessary that the region be deeply weathered and of gentle relief so that a mantle or segregation of resistant kyanite nodules, cobbles, and boulders can be accumulated at the surface. It is further necessary for labor to be abundant and cheap.

A great deal of literature has been published by the US Bureau of Mines, the US Geological Survey, and agencies of other governments describing investigations of kyanite-bearing schists. An exhaustive study was conducted by the USBM in Idaho on the huge deposits of kyanite, sillimanite, and andalusite at Goat Mountain and the kyanite deposit on Woodrat Mountain near Kemiah (Van Noy, 1970). Hundreds of millions of tons of 25% aluminum silicate ore available for surface mining has been postulated. However, remoteness from the major markets and the difficulty of beneficiation have stalled development at this locality.

Massive Kyanite—Kyanite is found locally as nodules, knots, and huge boulder-sized segregations in very highly metamorphosed areas of aluminous sediments. This had been the principal source of kyanite from India for the past 40 years. Similar segregations were the basis for the kyanite production in Kenya which has been discontinued.

In several counties in Georgia, similar lumps of massive kyanite are found (Furcron and Teague, 1945). While the abundance and purity of the Georgia massive kyanite meet the requirements for commercial exploitation, high labor cost makes economic production by hand-sorting and gathering unfeasible and production has been limited to a few carloads during World War II.

Kyanite mineral segregations are probably the result of local pneumatolytic migration of silica and alumina during the late stages of regional metamorphism. Introduction of alumina does not seem to have been a factor since the overall composition of the segregations are similar to that of the country rock if the sample area considered is large enough to include the barren quartz segregations which invariably accompany the kyanite-corundum segregations. Aside from the size and abundance of the segregations in the Lapsa Bura deposits of India, they do not seem mineralogically dissimilar from kyanite segregations found occasionally in all kyanite schists.

Massive kyanite typically contains corundum and minor amounts of rutile. The kyanite is often felty and acicular and occurs in tightly interlocking aggregates. Kyanites from India are usually produced in lumps large enough to be hand-

sorted according to kyanite and corundum content, and three grades are offered. Massive Indian kyanite has properties quite unlike that of large coarse kyanite crystals. Massive Indian kyanite is essentially volume-stable and calcines to a dense white aggregate that is much prized by European refractory manufacturers. On the other hand, the coarse kyanite produced from Georgia placer deposits in the 1940s, and more recently in Kenya, crumbles and loses much of its density and physical strength upon calcining. Apparently the interlocking acicular crystal mode of "Indian" kyanite prevents such expansion and consequent breakdown.

Sillimanite: Sillimanite Schists—Sillimanite is a very common rock-forming mineral in metamorphic rocks of relatively high rank. It is common in a series of metamorphosed rocks to find sillimanite, kyanite, and andalusite interchanging occurrences in given strata as the local conditions of temperature vary, as in the proximity to intrusives. For this reason the aluminum silicate minerals are often used to identify parameters of metamorphic intensity. Sillimanite, while common, seldom occurs as potentially exploitable crystals. The typical mode is what is often called "fibrolite" which is a felty aggregate of extremely fine "whisker" of acicular sillimanite interlaced and interlocked with quartz, mica, and other minerals. Beneficiation is usually impossible. In some areas the sillimanite occurs as nodules and buttons which are marginally potential as in the Peltzer area of South Carolina (Espenshade and Potter, 1960).

In Hart County, Georgia, there is a northeasterly trending zone about 16 km (10 miles) long in which "matchstick" sillimanite occurs. Beneficiation tests have been conducted, from which it appears that a limited production of sillimanite in the 35 mesh range could be accomplished. However, the deposits are narrow and limited, and there is presently no existing market or incentive for production of sillimanite concentrates in the United States (Furcron and Teague, 1945).

Massive Sillimanite—Massive sillimanite has been produced for many years from the state of Assam, India. Production has been falling off in recent years as the cost of production has risen and as other materials are substituted for the sawed blocks which were formerly an important use of sillimanite. The deposits of Assam consist of huge segregations of sillimanite and corundum, often in intimate association, and weighing several tons. Considerable hand effort is employed to recover the boulders in a form suitable for sawing to refractory shapes, particularly for the English glass industry.

In the vicinity of Adelaide, South Australia, late-stage metasomatism resulted in a mixture of kaolin and included boulders and nodules of sillimanite. The sillimanite is recovered as a byproduct in the process of manufacturing refractory clays. Other deposits of residual boulders of massive sillimanite have been exploited in this region. Beneficiation

has been tried with some success on the sillimanite itself and on the byproducts too low in grade to use directly. The Australian domestic market for such concentrates is limited, however, and thus far no large scale production has been reported.

The most important deposits of massive sillimanite-corundum occurs in the Republic of South Africa, in the Pella District near Pofadder, Namaqualand.

Andalusite: *Andalusite*—Andalusite is a frequent constituent of metamorphic rocks, although it is not as abundant or common as sillimanite or kyanite. It is found in argillaceous and micaceous slates, and in schists and gneisses resulting from the contact metamorphism of intrusive rock. Andalusite readily incorporates foreign matter in its crystals, and frequently grows around preexisting materials, including carbon. One variety, chialstolite, is so named for the crosslike inclusions of carbon oriented normal to the axis of the crystal.

In France, near Glomel in Brittany, an extensive, deeply weathered body of andalusite schist is being mined at the present time. Here the andalusite occurs as matchstick-sized crystals embedded in a fine-grained black groundmass composed of biotite, hornblende, muscovite, and feldspar. The andalusite is evenly disseminated and constitutes about 20% of the rock. The rocks in the area are very poorly exposed, and the geology of this occurrence is not well understood.

Near Canso, Nova Scotia, there is an extensive deposit of andalusite schist. Here the andalusite makes up about 15% of the rock and is evenly disseminated as large porphyroblasts averaging about 25.4×12.7 mm ($1 \times \frac{1}{2}$ in.) in cross section. The groundmass is principally muscovite, garnet, and feldspar. The crystals of black andalusite incorporate about 10% of finely disseminated magnetite and muscovite, however, and effective beneficiation is not practical.

Near Hillsboro, NC, a monadnock of andalusite-pyrophyllite-sericite rock is being mined by the Piedmont Minerals Co. The ore consists principally of pyrophyllite and quartz and contains 15 to 20% of disseminated pink andalusite. The andalusite is mined along with the pyrophyllite, and the resulting mixture is almost entirely consumed by the parent company in the manufacture of refractory products.

In the Goat Mountain deposit in Idaho, andalusite coexists with kyanite and sillimanite. No attempt has been made to separate it from the other aluminum silicate minerals in the tests made so far. The andalusite in this deposit typically incorporates a great many deleterious impurities. The Goat Mountain deposit is extremely large, but to date no commercial exploitation of the deposit seems feasible owing to beneficiation difficulties (Abbott and Prater, 1954).

Residual Andalusite—Alluvial deposits of andalusite sand occur in South Africa. These deposits have been worked on a very large scale. The source of the andalusite is shales of the Pretoria Series that have been intruded and metamorphosed by the Bushveld Complex. The andalusite has been weathered free from the parent rock and subsequently concentrated by the action of wind and water. Apparently concentration is still going on. The andalusite sand commonly contains 50% of recoverable andalusite. The reserves are estimated to be in the neighborhood of 800,000 tons of +50% andalusite. In 1964 a heavy media separation plant was installed, and since then the production of high grade concentrates has increased markedly.

Reserves

Domestic: The potential supply of kyanite minerals vastly exceeds the potential market. Therefore, what constitutes a reserve cannot be defined without considering the

probability of production. The two producing domestic kyanite deposits have enormous proven reserves. At least 65 million tons of kyanite quartzite containing at least 25% kyanite and amenable to surface mining were indicated by an extensive US Bureau of Mines drilling program undertaken in 1949 at Willis Mountain in Virginia (Jones and Eiletsen, 1954). The potential reserves in this locality are probably twice the indicated reserves. At Graves Mountain, geologic mapping and diamond drilling has indicated a reserve of 25% ore in excess of 30 million tons. From these figures, which translate into many decades of production at current rates, it is readily apparent that the existing producers have little interest in acquiring new reserves unless a considerable economic advantage would result. If the +10% kyanite-bearing schists and gneisses are included, the reserves in the United States and Canada are truly vast. At current prices these reserves are obviously submarginal.

World: Most of the comments made about the reserves of kyanite minerals in the United States apply to other areas of the world as well. However, the massive kyanite reserves of India, being relatively rare and unique in occurrence, are more susceptible to reserve considerations. The Lapsa Buru area is credited with 700,000 tons of massive kyanite to a depth of 3 m (10 ft), and the Madhya Pradesh area with 250,000 tons of massive sillimanite.

In the Republic of South Africa, 800,000 tons of +50% andalusite sand are reported for the Transvaal and millions of tons of sillimanite reserves have been credited to Namaqualand in the Cape Province.

No figures have been reported from the Province of Brittany, France, where andalusite is produced. However, the body of andalusite schist is reported to be at least 1 km wide and about 10 km long, and to contain an average of about 15 to 25% andalusite. This translates into many tens of millions of tons of potential reserves.

It is apparent that the existing producers of aluminum silicate minerals have adequate reserves, with the possible exception of the unique and relatively rare deposits of massive kyanite-corundum and massive sillimanite-corundum. It should be noted, however, that the primary use for the massive varieties is being increasingly challenged by the more consistent synthetic mullite materials which are produced from more available high alumina clays and bauxite.

The heavy mineral beach sand deposits of the world generally contain a significant proportion of andalusite, sillimanite, or kyanite. The US Bureau of Mines has described a method of producing a kyanite coproduct from the ilmenite sand treatment plants in Florida. The potential production from heavy mineral deposits throughout the world is large.

Exploration and Evaluation

Kyanite and sillimanite are fairly common minerals, and are found in the metamorphosed rocks on every continent. Andalusite is less abundant but still common. However, kyanite is consumed principally by the highly developed industrialized nations and its consumption is therefore restricted to certain areas. For example, the bulk of the American production of kyanite is consumed in a relatively small region extending from the northeastern part of the United States to central Missouri. A similar pattern exists in Europe, where consumption is concentrated in those parts of England, France, and Germany where the producers of refractories are concentrated. Kyanite and related minerals must be delivered to the consuming areas at competitive prices. Therefore, a very important preliminary consideration in any exploration project is the prospective cost of delivering

the kyanite to the market. In the United States, typical freight costs for delivering kyanite concentrates from traditional sources to consumers ranges between \$30 and \$40 per ton. A relatively small market exists on the west coast of the United States where the freight is as high as \$90 per ton.

The second problem to be considered is the probability of producing a salable product. Kyanite consumers are notoriously finicky about the specifications of materials used by them in the manufacture of refractory products. Thus any deviation from the commonly accepted specifications imposes a considerable burden on products attempting to enter the market. Probably the most important consideration is this regard when evaluating a raw prospect is the liberation size of the kyanite crystals. In the western United States there are several otherwise attractive kyanite-quartzite deposits which cannot be beneficiated to the required specifications without grinding the ore to about -200 mesh, which is quite fine considering that most existing kyanite deposits can produce concentrates in a size range of at least -35 to 28 mesh.

If the initial investigation indicates that both freight and quality of product can be competitive, then the normal exploration techniques apply. These consist of surface sampling, trenching, geologic mapping, and some limited diamond drilling to test the material in depth. Kyanite deposits are in reality kyanite-bearing rocks produced by regional metamorphism. They have inherently consistent compositions, unlike the hydrothermal deposits which are typical of the precious and base metals. Geochemical and geophysical exploration techniques are generally not useful for evaluating kyanite and other aluminum silicate deposits.

After a deposit has been explored, the potential markets determined, and studies indicate that a competitive product could be produced and delivered to the market, the next step should be a pilot plant production of the material intended to be marketed. Bench scale and laboratory testing are not sufficient in this regard. As an example, in recent years a major attempt was made to produce kyanite from schists and kyanite-bearing gneisses in Canada. After the construction of a plant and the expenditure of a great deal of money it was found that a salable concentrate could not be produced economically. Similar failures have occurred in the United States and in other countries. Therefore, it is most important to produce, by reproducible pilot plant techniques, a quantity of concentrates from a representative selection of ores sufficient to permit prospective consumers to test the new material extensively in their plants. There is no laboratory substitute for this kind of field testing in the plants of the intended consumers. Quoted physical and chemical specifications are to be used only as approximations of the suitability

of a given kyanite or aluminum silicate material. New producers of aluminum silicates have found to their sorrow that kyanite conforming to specifications supplied by the prospective consumers may not in fact be what those consumers are really willing to use when confronted with the decision to utilize a new material from a new area. Competitive testing and specific approval is the only sure way that the marketability of a given kyanite concentrate can be assured.

11. Limestone and Dolomite*

DONALD D. CARR

INTRODUCTION

The physical and chemical properties and widespread distribution make limestone and dolomite so useful that in 1987 more than 764 mt (840 million tons) of these minerals were produced in the United States. They were produced in 46 of the 50 states and ranked second to sand and gravel in total tonnage.

About 75% of the land surface of the world is sedimentary rock, and limestone and dolomite compose about 20% of that area. Limestone and dolomite are exposed near the surface on all continents and range from Precambrian to Recent in age. Reserves are so large that the numbers become meaningless, but these reserves are not always where they are needed. For some uses, such as aggregates, other materials can substitute for limestone and dolomite, but, for uses requiring certain chemical properties, substitution may not be viable.

Although limestone and dolomite are distinctly different rocks with different mineralogical, chemical, and physical properties, they have many common characteristics. They are closely associated with each other in the geologic environment; some operators mine both in the same quarry. They are mined, processed, and transported in the same way. And they substitute for each other for many uses. Throughout this article the term "limestone" will be used for both limestone and dolomite unless a clear distinction is necessary.

DESCRIPTION

Mineralogy

Limestone is a sedimentary rock composed of more than 50% of the mineral calcite (CaCO_3); dolomite is composed of more than 50% of the mineral dolomite ($\text{CaMg}(\text{CO}_3)_2$). Aragonite has the same chemical composition as calcite, but it has a different crystal structure. It is important only in such modern deposits as oolites or oyster shell because aragonite is metastable and alters to calcite with time. Impurities are indicated by a qualifying adjective. For example, limestone with appreciable clay is designated as an argillaceous limestone. Crystal form, color, specific gravity, and other physical properties are important in the mineral identification of specific carbonate species (Table 1).

Chemical Properties

Although the chemical and physical attributes are independent properties, a carbonate rock is seldom considered only for its chemical properties. For most uses in which chemical attributes are specified, however, the degree of purity stands as the most important property. The chemical requirements for some uses do not easily fit into a pigeonhole classification. Although the minimum composition may indeed need to be specified, classification is useful for discussion

Table 1. Physical Properties of Calcite, Dolomite, and Aragonite.

Mineral	Chemical Composition	Physical Properties
Calcite	CaCO_3	Hexagonal crystal system, commonly good rhombohedral cleavage. Mohs hardness, 3. Specific gravity, 2.72. Commonly colorless or white but may be other colors because of impurities.
Dolomite	$\text{CaMg}(\text{CO}_3)_2$	Hexagonal crystal system, commonly good rhombohedral crystals with curved faces. Mohs hardness, 3.5 to 4. Specific gravity, 2.87, but common impurities such as iron can raise it to 2.95 or higher. Commonly white or pink.
Aragonite	CaCO_3	Orthorhombic crystal system. Mohs hardness, 3.5 to 4. Specific gravity, 2.93–2.95. Commonly colorless, white, or yellow but may be other colors because of impurities.

and evaluation. The terminology used in this article is as follows:

High-calcium limestone: greater than 95% CaCO_3
High-magnesium dolomite: greater than 42% MgCO_3
High-purity carbonate: greater than 95% combined CaCO_3 and MgCO_3

Accurate chemical determinations in ranges greater than 95% CaCO_3 are difficult and should be entrusted only to a reliable laboratory. A useful list of testing companies capable of making chemical and physical determinations of carbonate rocks can be found in the *Directory of Testing Laboratories, Commercial-Institutional* (American Society for Testing and Materials, 1987).

Physical Properties

Although the suitability of a carbonate rock for industrial use may hinge on a small difference in chemical composition, the suitability based on physical properties is less demanding. Some physical testing is done by duplicating actual use conditions, but if actual use is not practical because of limited time or difficulty in duplicating the conditions, tests designed to correlate with actual use conditions are preformed. An example of the former is the burning of stone at calcination temperatures to measure decrepitation effects, and an example of the latter is the battery of physical tests for aggregates to measure the durability of stone during extended use and in certain weather conditions. Physical testing is described in detailed procedures from two main sources: the American Society of Testing and Materials (ASTM) and the American Association of State Highway Officials (AASHTO). Organizations that purchase aggregates generally follow the specifications given in AASHTO and those that purchase dimension stone follow ASTM.

* In part from Carr and Rooney (1983). Curtis H. Ault and Brian D. Keith, Indiana Geological Survey, and Garland R. Dever, Jr., Kentucky Geological Survey, provided useful review and comment.

ORIGIN

Although carbonate sedimentation occurs in both fresh-water and marine environments, the volume of freshwater carbonate is negligible; deposits of economic importance are almost entirely marine. Within the marine environment, carbonate deposition ranges from foraminiferal oozes in the deep sea floor to the fine-grained micritic algal mats of the supratidal environments. But probably the deposits of greatest economic value, because of their abundance and relative purity, are those that form on shallow-water banks of tropical areas in settings that are often referred to as carbonate factories. It is in these areas where optimum conditions exist for organic activity and organisms whose shells make up the deposits live in abundance. It is also where high-energy currents winnow out fine impure particles so they are not deposited with the carbonate.

In simplistic terms the environment of deposition and the organic community largely determine the geometry of the carbonate deposit. In some places lime-secreting organisms, such as corals, calcareous algae, and mollusks, are able to erect large wave-resistant structures, called reefs. As the reef grows, colonies of corals secrete calcium carbonate and attach their shells to the dead corals below. Where the waves break up the coral masses, debris is carried to the flanks and deposited in quieter water, building up steeply dipping beds of relatively pure carbonate grains. Many other calcareous-secreting organisms live in and around the reef and add to the mass of carbonate. Throughout the higher energy areas the skeletal parts may be broken up and moved by wave action until the delicate balance between grain size and current strength changes to allow deposition. It is generally in these high-energy zones where the carbonates are relatively pure and the finer impure clays and silts have been removed by currents to quieter areas for deposition.

Environment of deposition is significant to the economic geologist because it determines the size, shape, purity, and other economically significant characteristics of the carbonate-rock deposit. Limestones that form in high-energy zones generally contain little noncarbonate material and so may be the source of high-purity carbonate material. Micrite, which accumulates in zones of low energy, can be diluted by clay and silt-size noncarbonate material, although some micritic supratidal low-energy carbonates can be pure when no land sources of clay or silt contaminants are nearby.

Carbonate sediments are highly susceptible to postdepositional alteration and modification through chemical diagenesis. The origin of dolomite is especially significant to the economic geologist. Virtually all dolomite is a result of the alteration and recrystallization of calcium carbonate sediments or rocks by magnesium-bearing fluids, and very little dolomite may be precipitated directly from seawater. The mechanism of dolomite formation is not well understood, but, by whatever process, some magnesium ions can substitute for calcium ions in the calcite structure and convert it to dolomite. Good examples are the almost-pure dolomitic Silurian reefs in northern Illinois, Indiana, and Ohio and in southern Michigan.

DISTRIBUTION

Carbonate rocks suitable for most construction uses are widespread, but those of high chemical purity are more restricted in their distribution. Virtually all states except Delaware, Louisiana, New Hampshire, and Rhode Island (Table 2) and all Canadian provinces have potentially commercial deposits of high-calcium limestone and (or) high-magnesium

dolomite. Twenty-one Mexican states have had production of high-calcium limestone or high-magnesium dolomite in recent years. Literature describing locations are given by Carr and Rooney (1983, Table 2).

Because deposits of carbonate rocks are present, however, does not necessarily mean that they can be exploited. In many areas competition is intense for potential mineral lands for construction sites, recreation areas, and highways; even nature has her own requirements for flowing streams, glacial cover, and soil development. People who have benefited by low-priced aggregates and building stone and have built homes in rural areas now look askance at quarries in their backyards. Society has imposed environmental controls, now firmly ensconced in state and federal statutes, that prohibit or restrict mineral production in areas where it might significantly affect the quality of the environment.

EXPLORATION

Exploration for limestone and dolomite in North America is largely the detailed examination of known deposits. Because limestone is a sedimentary rock, it occurs in strata generally of considerable areal extent, but the chemical and physical properties vary greatly in both lateral and vertical extent. Some data as to chemical composition and physical character are available for most such strata in the published reports or files of state, provincial, and national geological surveys. Most exploration for a new limestone deposit, therefore, begins with a search of these records to find the locations of deposits that satisfy the various economic factors and proceeds to a sampling program of favorable deposits. Geophysical techniques, if used at all, are used to determine the thickness of overburden. Geochemical techniques are not used.

All aspects of exploration are important, but the one most likely to be slighted is sampling. This is in spite of its importance in determining the validity of further study, for it may become the basis for hundreds of thousands and sometimes millions of dollars worth of development work. Its goal must be the accurate representation of the limestone deposit. Coring, rock biting, and surface (ledge) sampling are the most common methods, and the choice among these depends on such matters as the geology of the deposit, the proposed use of the material, and the availability of equipment.

Special care should be taken when sampling weathered outcrops. In humid regions the surface layer of a carbonate rock may be leached of calcite and dolomite and therefore be less pure than the rest of the unit. On the other hand, in arid and semiarid regions, where evaporation exceeds precipitation for long periods of time, the surface layer may be enriched in calcite and dolomite. If surface samples must be taken under these conditions, the geologist should be aware of a potential bias.

Limestones used commercially are usually deposited in marine basins and across broad areas and have good lateral continuity. In the Pennsylvanian coal-bearing rocks of the Midcontinent, the marine limestones and shales as well as the coals are favored for correlation. But different depositional environments exist over these broad depositional areas and result in many different limestone types. Cressman (1973) has documented lateral variation and intertonguing of different types of limestone within a limestone formation.

Recognizing the depositional environment is a key in the exploration of limestone because it governs geometry, distribution, and composition of the various limestone types. Generally within a particular type of environment some consistency of properties can be predicted to enable the geologist

Table 2. Principal Sources of High-Calcium Limestones and High-Purity Dolomites in the United States

United States	Stratigraphic Unit	Limestone (L) or Dolomite (D)	Age

† Potential commercial sources are not present.

in planning the necessary sampling locations. In flat-lying rocks only a few drill holes may be needed, but in structurally altered areas many are required.

Carr (1973) found that individual high-calcium oolitic units in the Illinois Basin ranged from 0.8 to 3.2 km (0.5 to 2 miles) wide and as much as several miles long. The bodies were lenticular and as thick as 7.5 m (25 ft). Ault (1986) and Ault and Carr (1981) reported that in the Great Lakes area of northern Illinois, Indiana, and Ohio and in southern Michigan, reefal deposits, which are sources of high-purity carbonate rocks, ranged in size from 30 to 60 m (100 to 200 ft) in diameter and less than that in thickness to more than 15 km (9 miles) in diameter and 120 m (400 ft) in thickness. These reefs are commonly surrounded by interreef limestones and dolomites that have limited use as aggregates.

In structurally complex areas the variation in depositional environment as well as the structural component must be considered. Brown (1966) reported that in some Lower Devonian carbonate rocks used for cement raw material in the central Hudson River Valley, drill spacings of 60 by 120 m (200 by 400 ft) were necessary for quality control. Banino (1980) reported that in the Lehigh Valley, Pennsylvania, detailed mapping at a scale of 2.54 cm to 30.48 m (1 in. to 100 ft) was necessary in a complexly interfolded and faulted section of Cambro-Ordovician carbonate rock.

MINING

Limestone is mainly produced by open-pit and underground mining, but some modern deposits, such as shell and oolites, are produced by underwater dredging. The largest tonnage of stone is produced by open-pit mining because it

is generally less expensive than underground mining, but reasons for underground mining can be compelling. Rooney and Carr (1971) summarized the advantages of underground mining as follows:

- Lack of near-surface deposits may make underground mining the only method.
- Unfavorable geologic structure may require that a surface mine move underground to follow a particular bed.
- More efficient use of reserves may be possible by underground mining in areas where overburden removal may make surface mining impractical.
- Underground mining may permit selective mining of a particular bed without removal of, or contamination by, the overlying materials or clay seams.
- Underground mining may permit all-weather mining and provide greater economies through year-around operation.
- Underground mining is more inconspicuous than open-pit mining, a factor that may lessen environmental problems. Underground mining may be feasible in urban areas where the surface is expensive or preempted for other uses.
- Underground mining may provide space for secondary uses, such as manufacturing, offices, storage, and waste disposal.

Open Pit

The techniques vary, depending on whether the product is crushed stone or dimension stone, but for both the first step is the removal of overburden to gain access to the stone to be quarried. Where overburden consists of soil or unconsolidated material, a bulldozer, a dragline, or a scraper may

be used, but if the material is consolidated, blasting may be required to ease removal. For some dimension-stone operations, blasting is used little or not at all for fear of fracturing the stone below. Some care must be given to overburden removal; partial removal may lead to problems of contamination of the product, clogging of screens and other processing equipment, or unsafe working conditions for employees. In areas where solution may have produced grikes or solution features in the limestones, some hand dental work may be required to prepare the top ledge for removal.

In crushed-stone operations blasting is used not only to free the stone from the ledge but also to form the first stage of stone fragmentation. The material is then transported, generally by front-end loader, truck, and (or) belt conveyor, to a processing plant for final crushing, sizing, and stockpiling.

In dimension-stone operations the stone is set free from the ledge by some type of sawing or cutting device. Channeling machines, wire saws, and chain saws are the types most commonly used to make vertical cuts in the stone. If the stone does not have a natural bedding plane to allow separation of the base of the block, sleeved wedges may be driven into closely spaced horizontal drill holes. Once the stone is free on all sides, it can be tipped forward (turned down) and sectioned into mill blocks of desired size by using sleeved wedges in drill holes. The mill blocks are then transported to a staging area for drying (curing) before delivery to the mill for fabrication.

Underground

The techniques also differ for underground mining depending on whether the use is for crushed stone or dimension stone. For either use some access to the mining seam must be obtained; vertical shaft, slope, or horizontal drifts are used depending on conditions.

In crushed-stone operations some form of room-and-pillar mining is used, but whether the pillars are square, round, or elongate may depend on mining conditions and post-mine-

use plans (Aughenbaugh, Christiansen, and Scott, 1974). Mine orientation and pillar design and configuration may depend on jointing and other structural considerations (Ault and Haumesser, 1989). The mine is generally developed by a heading-and-bench system, and the stone is brought to the surface for final processing and stockpiling.

Underground mining of dimension stone is less extensive in the United States than in Europe, but its popularity is sure to grow because of environmental and land-use considerations. Where underground mining is feasible a room-and-pillar method is used. The stone is cut from the mining seam by using a chain saw, called a gallery saw, capable of horizontal as well as vertical cutting. Underground mining holds promise of year-long operation, improved ability of removing only desirable blocks without removing excessive overburden, and reduced impact on the surface environment. Blocks quarried underground can be cured underground without fear of damage by freezing and then transported to the mill for processing.

USES

The uses of limestone and dolomite depend on the physical properties, chemical properties, or both. Physical properties are more important if stone is used "as is," such as for aggregate or building stone. Chemical properties are more important if stone undergoes changes from one form of matter to another, such as for manufacturing cement or lime. Chemical and physical properties are often interrelated; in whiteness, for example, the physical property of color is largely determined by the purity and chemical composition of the rock.

Limestone and dolomite account for about three-fourths of all crushed stone used in the United States; they account for less than one-third of the dimension stone (Fig. 1). Although limestone and dolomite have hundreds of uses, many of which are reported in Lamar (1961) and Siegel (1967), more than half of the tonnage produced each year is for construction aggregates (Table 3). The distribution of natural

aggregates in the United States was described by Langer (1988).

BYPRODUCTS AND WASTE MATERIALS

Crushed Stone

Removal and disposal of overburden are challenges facing operators of all crushed-stone operations. In most operations the overburden is wasted, but ideally, with a good mine plan, the material is placed where it will not need to be moved twice. In the startup of any open-pit operation the overburden must be removed to expose the mining seam. This material may be used for berms to create visual or sound barriers, which help with the attractiveness of the operation. As an alternative, the material may be stockpiled for future reclamation use by grading and seeding so as to prevent erosion and loss. In a few places overburden may have value for brick, cement raw materials, or fill.

Excess fines that may have potential use for other products are created in crushing limestone. The fines will generally have a composition different from that of the limestone being crushed because they contain the shale and soft material that pass through the screens. In agricultural areas fines generally work well for agricultural limestone. Although specifications vary from state to state, the requirements for agricultural limestone are sufficiently broad to allow the fines to be used without further processing. Fines may also be used for low-grade fillers and for some scrubber materials for stack-gas cleaning. In cold climates shipping of fine materials may be a problem because of the difficulty of unloading at the destination.

Dimension Stone

Overburden removal creates the same problem for dimension-stone quarries as for crushed-stone operations, but

an added problem is waste blocks. In most quarries the upper ledge must be wasted because of imperfections in the stone, and these blocks must be removed from the ledge in the same manner as good-quality stone. The dimension-limestone industry has long been characterized by a high ratio of waste materials to salable prime product, both in quarrying and in fabrication. In the Indiana building-limestone district, the principal visual evidence has been the grout piles of overburden and unused building stone. For years it has seemed to the public that blocks and coarse waste fragments, once quarried, should have some use, and many ideas have been advanced and attempts made to salvage the waste material for some purpose that would repay at least a part of its cost (Patton and Carr, 1982). The most common suggestion has been that it should be possible to crush the stone for one of the many purposes to which aggregates are put, but the waste is generally not well suited to most crushed-stone uses, and the cost of reworking the old grout piles is greater than the cost of obtaining new stone, freshly quarried by conventional crushed-stone practices. The size of the waste blocks induces handling and crushing expenses greater than the potential yield in dollars.

Some use of waste blocks has been made for breakwater and seawalls, but even for these uses flaws in the stone may make the stone unsuitable. Also, because the blocks are large and heavy, transportation costs are important. In areas near quarries, waste blocks and lapies have found use as lawn sculpture and ornamentation, and in one area near Oolitic, IN, an unsuccessful attempt was made to create a 29-meter-high (98-ft-high) pyramid, patterned at one-fifth scale after the Great Pyramid of Cheops. But all of these minor uses fail to dent the great grout piles that cover the landscape.

SOURCES OF INFORMATION

Publications of state geological surveys or their equivalents are the best references for information on the common industrial minerals and rocks. Most state publications are oriented toward areal geology, mineral resources, or the two combined rather than toward uses or methods. Some state publications purportedly on commodities contain valuable information on uses. Many states have geologic maps that show distribution of limestones, but the number that has published quadrangle maps (1:24,000 scale), the most useful for prospecting, is limited. Kentucky and Rhode Island are the only states to have complete coverage; some states have unpublished quadrangle maps on open file that are useful.

The US Bureau of Mines and US Geological Survey also publish information on limestone and dolomite, and their publications are useful for mineral statistics, mining characteristics, broad overviews, and, in some reports, site-specific information. Trade publications, such as *Rock Products*, *Pit and Quarry*, and *Industrial Minerals*, are good sources of information on specific mineral producers, plants, specifications, and trends in the industry.

Two professional organizations, which have meetings with consistently high-quality presentations on limestone, are the Industrial Minerals Division of the Society of Mining Engineers (SME) and the Forum on Geology of Industrial Minerals. Some papers presented at SME meetings are selected for publication in the Society's publications, *MINING ENGINEERING* and *Transactions*. The Forum is hosted each year by a different state geological survey. Most papers presented at the Forum appear in a proceedings volume, published by the host organization.

In the late 1950s and early 1960s oil companies began to concentrate research on carbonate rocks because of economic incentives. As a result, useful material was published on composition and texture (Ham, 1962; Scholle, 1978) and on depositional environments (Friedman, 1969; Scholle, Bebout, and Moore, 1983). Numerous articles and volumes that contain much useful information on limestone as a commodity and on the industry that produces it have been written. *Industrial Minerals and Rocks* (5th edition, 1983) has articles on "Limestone and Dolomite" (Carr and Rooney, 1983) and on "Lime" (Boynton, and others, 1983) as well as articles on crushed-stone uses that include limestone and dolomite, such as "Aggregates—Crushed Stone" (Schenck and Torries, 1983) and "Cement and Cement Raw Materials" (Ames and Cutcliffe, 1983). A useful handbook for quarry operators (Lamar, 1967) contains much information of interest to the general public.

Although designed as a textbook for the teaching of a course in industrial minerals, *Geology of the Industrial Rocks and Minerals* (Bates, 1969) contains useful information on selected limestone deposits. *Geology of the Nonmetallics* (Harben and Bates, 1984) has a chapter on "Limestone and Dolomite" that covers applied aspects of interest to industry, and *Industrial Minerals and Rocks* (Kuzvart, 1984), a handbook with a European perspective, has sections on limestone and dolomite. Broad coverage of limestone and dolomite in the United Kingdom is provided by Harris (1982), and a regional assessment is provided by Harrison and McL. Adam (1985). The most comprehensive volume to cover limestone and its use as lime is *Chemistry and Technology of Lime and Limestone* (Boynton, 1980). The *Concise Encyclopedia of Mineral Resources* (Carr and Herz, 1989) gives comprehensive coverage for the various uses of industrial minerals of which limestone and dolomite are important commodities.

The properties of limestone that make a good crushed-stone aggregate are different from those for dimension stone; even the exploration, quarrying, processing, transportation, and marketing are different. Comprehensive coverage of these various aspects can be found in Barton (1968), Cox, Bridge, and Hull (1977), Currier (1960), Honeyborne (1982), Leary (1983), Patton and Carr (1982), Power (1983), and Rooney (1970).

12. Lithium Raw Materials*

INTRODUCTION

Lithium minerals occur predominantly in pegmatites which contain mineral assemblages derived from the crystallization of postmagmatic fluids or from the metasomatic action by residual pegmatitic fluids. They have been the traditional sources of raw materials for ceramic and chemical industries. With the discovery of Searles Lake, brines became new sources of lithium.

Indeed, the 1960s may well be referred to as the "brine decade" because several brine bodies of significant economic importance were discovered. In the United States, the brines of Clayton Valley, Nevada, are presently exploited by Foote Mineral Co. The brines of the Great Salt Lake of Utah, the Smackover formation, and the Imperial Valley geothermal field, have been defined as important resources of lithium. In South America, new occurrences have been identified in Bolivia and Argentina. At the Salar de Atacama, Chile, new production capacity was scheduled for 1984.

Following the termination of the AEC purchase program in 1959, several companies such as Maywood Chemical Co., American Lithium Chemicals, and Quebec Lithium Corp. were forced to close their operations. Nevertheless, with the development of new applications in glass ceramics, air conditioning systems, synthetic rubber, and metallurgy (aluminum potlines), the lithium industry grew steadily, and with the potential application of lithium metal in batteries and nuclear reactors, a healthy growth can be foreseen. New products and new applications are likely to stimulate exploration for expanded reserves as well as the search for new sources from which lithium could be extracted economically.

GEOCHEMISTRY OF LITHIUM

Lithium is the third element in the periodic table. It is the lightest of all the metals, having an atomic weight of 6.938, an ionic radius of 0.68Å, and a charge of +1.

The geochemistry of lithium has been extensively studied and has been summarized by Rankama and Sahama (1950), Goldschmidt (1937), and Hortsman (1957).

The distribution of lithium in igneous rocks is controlled by its size and its charge, and by the $(\text{MgO} + \text{FeO})/\text{Li}_2\text{O}$ ratio. In the early stages of crystallization of a magma, that ratio is very large. Consequently, both magnesium and iron are removed by ferromagnesian minerals in preference to lithium which is then concentrated in the residual magma. This results in an enrichment of lithium in silicic rocks and pegmatites (Strock, 1936).

Pegmatites are coarse-grained igneous rocks formed by the crystallization of postmagmatic fluids. Minerals within pegmatites may also form by metasomatism (Jahns, 1955). Genetically, the pegmatites are associated with neighboring intrusives. Mineralogically, granitic pegmatites contain feldspar, quartz, and mica as the main constituents and a variety of exotic elements such as lithium, beryllium, tantalum, tin, and cesium, which may or may not occur in economically significant concentrations.

Detailed studies by numerous investigators (Cameron, et al., 1949, 1954; Hanley, et al., 1950; Jahns, 1953, 1955; Page,

et al., 1953) indicate that pegmatites often exhibit an internal zonal arrangement, with each zone containing a specific suite of minerals. The lithium minerals are usually found in the intermediate zones, and although as many as 13 zones have been recognized by Cameron, et al. (1949), a complete zonal arrangement is rarely found. Zoning of pegmatite bodies has also been observed on a regional basis. The regionally zoned pegmatite sequences exhibit mineral assemblages and complexity according to their respective distance from the granitic bodies to which they are genetically related.

Lithium is also found in small proportions in a variety of rocks. The average lithium content of igneous rocks is estimated at about 28 ppm Li. Sedimentary rocks contain an average of 53 ppm Li, the highest being recorded in shales (Hortsman, 1957).

Unusual amounts of lithium are found in the clay mineral, hectorite, which is expandable and belongs to the magnesian end member of the smectite group. Recent work by the US Geological Survey suggests that lithium-rich clays are ubiquitous in a number of clay environments.

Lithium is also present in significant amounts in waters associated with geothermal areas (White, 1957), in oil well brines (Mayhew and Heylman, 1966), and certain brines of California (Searles Lake), Nevada (Clayton Valley), Utah (Great Salt Lake), and Chile (Salar de Atacama), Bolivia (Salar de Uyuni), and Argentina.

LITHIUM MINERALS

Although lithium occurs in some 145 minerals, only spodumene, lepidolite, petalite, amblygonite, and eucryptite have been commercial sources of lithium.

Spodumene, a lithium aluminum silicate ($\text{LiAlSi}_2\text{O}_6$), is a monoclinic member of the pyroxene group. It has a very pronounced cleavage plane (110) which results in typically lath-shaped particles upon breaking. The color of spodumene is variable, being nearly white in low iron variety and dark green in iron-rich crystals.

When clear, spodumene is considered a gemstone. Three varieties are known: *hiddenite*, the green variety from Alexander County, North Carolina, first discovered in Brazil; *triphane*, the yellow variety also from Alexander County; and the lilac-colored *kunzite* from the Pala district, California, Brazil, and Afghanistan.

Spodumene undergoes pseudomorphic alteration to a variety of minerals. Norton and Schlegel (1955) have described spodumene replacement by quartz, albite, perthite, muscovite, beryl, amblygonite, apatite, and tourmaline. Weathering commonly alters spodumene to kaolinite and to montmorillonite.

Spodumene constitutes the most abundant commercial source of lithium. Theoretically, it may contain up to 3.7% Li, but the actual lithium concentrations vary from 1.35% to 3.56%, probably as a result of sodium and potassium substitution for lithium. Spodumene concentrates typically contain 1.9% to 3.3% Li.

Lepidolite is a phyllosilicate with the general formula $\text{K}_2(\text{Li},\text{Al})_{5-6}\{\text{Si}_{6-7}\text{Al}_{2-1}\text{O}_{20}\}(\text{OH},\text{F})_4$. The chemical variability expressed in the formula stems from a structural complexity attributed to a mixture of different polymorphs which include muscovite, lithium muscovite, and polyolithionite (Winchell, 1942). On the other hand, Foster (1960) and Deer, et al.

*Excerpt from Kunasz, I.A., 1983, "Lithium Raw Materials," *Industrial Minerals and Rocks*, 5th ed., Vol. 2, S.J. Lefond, ed., AIME, New York, pp. 869-880.

(1962) suggest that there is a continuous series between muscovite with a $2M_1$ structure to lepidolite, with $1M$, $2M_2$, and $3T$ structures. The structural transition takes place when the lithia content in the mica reaches 1.53%.

The lithium concentration in lepidolite varies between 1.53% to a possible theoretical maximum of 3.6%. In commercial deposits, the concentrations are more normally 1.4% to 1.9% Li. In addition to lithium, lepidolites also carry substantial concentrations of rubidium and cesium (Deer, et al., 1962).

The major commercial occurrences of lepidolite are located in Zimbabwe (Bikita), Namibia (Karibib), Canada (Bernic Lake, Manitoba), and Brazil.

Petalite, $LiAlSi_3O_{10}$, is a monoclinic mineral with a framework silicate structure. Its color is grayish white and more rarely pinkish. It has two cleavage directions which form an angle of 38.5° . The basal cleavage is perfect.

The theoretical lithium content of petalite is 2.27%. In actual commercial deposits, the concentration varies from 1.6% to 2.1% Li. Sizable deposits of petalite occur with lepidolite in Zimbabwe (Bikita), Namibia (Karibib), Brazil (Araçuaí), Australia (Londonderry), in the USSR (eastern Transbaikalia), and Sweden (Utö).

In certain pegmatites, there is evidence that petalite alters to a mixture of spodumene and quartz. In the Bernic Lake pegmatites of Manitoba, Cerny, et al. (1971) have described pseudomorphs of spodumene and quartz after petalite.

Eucryptite is also a lithium aluminum silicate which is deficient in silica. It has a formula $LiAlSi_3O_8$ and may contain 5.53% Li. The only large deposit of eucryptite is found in Zimbabwe (Bikita) where its occurrence with quartz suggests a spodumene origin (Westenberger, 1963). The grade of the eucryptite is 2.34% Li.

Amblygonite, with the generalized formula $LiAl(PO_4)(F,OH)$, is the fluorine-rich end member of a phosphate series, while montebrasite represents the hydroxyl-rich end member. It occurs in white to gray masses. Basal cleavage planes are pearly, others are vitreous. Amblygonite weathers to earthy apatite, wavellite, and other lithium deficient phosphates. Although amblygonite may contain as much as 4.74% Li, commercial ores usually carry 3.5% to 4.2% Li. Amblygonite has been mined in Canada, Brazil, Surinam, Zimbabwe, Ruanda, Mozambique, Namibia, and the Republic of South Africa.

Brines. Lithium is found in commercial quantities in certain brine deposits. The brines are present in desert areas and occur in playas and saline lakes where solutions have been concentrated by solar evaporation. In Searles Lake where production of dilithium phosphate began in 1938, the lithium concentration is 70 ppm Li. In Clayton Valley, Nevada, lithium-bearing brines contain 200 ppm Li. Smaller concentrations of lithium (28 to 60 ppm Li) are found in the Great Salt Lake. Rich concentrations of lithium have been identified at the Salar de Uyuni in Bolivia (100-700 ppm) and the Salar de Atacama in Chile (1000-5000 ppm).

RESERVES

Projections of lithium metal requirements to satisfy the needs of the automotive and storage battery system as well as the potential use in thermal nuclear fusion energy generation resulted in concern regarding the availability of sufficient lithium. The US Geological Survey created the Lithium Exploration Group, which subsequently sponsored two symposia, one held in Denver, CO and another in Corning, NY. Concurrently, the Energy Research and Development Administration requested the National Academies of

Sciences and Engineering to form a National Research Council Committee on Nuclear and Alternative Energy Systems (CONAES). One of the groups was the Lithium Subpanel consisting of experts from the industry and the government, formed to evaluate the lithium availability in the western world. The results of the Subpanel study were presented at the second lithium symposium held at Corning, NY in 1977. This document is considered the best reference regarding reserves and resources and the serious student of lithium should have this particular publication on hand (Penner, 1978). Many of the figures quoted in this review have been taken from the Subpanel study.

MAJOR PRODUCING DISTRICTS

At the present time, the United States and Zimbabwe supply the bulk of the free world's demand for lithium raw materials, and the United States is the leading producer. Within the communist bloc, the Soviet Union probably represents an important producer; production figures, however, are not available. The People's Republic of China is reported to produce lithium compounds from ores mined in the north-western part of the country.

United States

Lithium ores and lithium chemicals in the United States are supplied by three producing areas. Two of the areas are in the tin-spodumene belt of North Carolina, while brines are exploited in Clayton Valley (Silver Peak), Nevada.

The tin-spodumene belt of North Carolina constitutes the largest developed reserve of lithium in the free world. The area is characterized by numerous pegmatites that intrude amphibolites and schists along the eastern margin of the Devonian Cherryville quartz monzonite (Kesler, 1961).

The pegmatites are typically unzoned, and spodumene is distributed throughout the bodies. The contact zones and aplitic layers contain substantially lower percentages of spodumene. On the average, the pegmatites consist of 20% spodumene, 32% quartz, 6% muscovite, 41% feldspar (including albite and microcline), and about 1% trace minerals, such as beryl, lithiophilite, columbite, tantalite, pyrite, sphalerite, apatite, and rhodochrosite (Kesler, 1961).

The tin-spodumene belt has a length of about 48 km (30 miles) and the exploration activity has been restricted to the upper 300 m (984 ft). The geological setting and distribution of pegmatites suggest that pegmatites may well occur at greater depth. Kesler, in a study of the potential lithium contained in the total belt down to a 1.5 km (4921 ft) level, has suggested the potential existence of a resource of 754 million tons at a grade typical for the area.

Other known pegmatite sources in the United States are not of great significance. These include the Black Hills of South Dakota, the Pala district of southwestern California, the White Picacho District of Arizona, the Harding and Pidlite mines in New Mexico, and several smaller areas in Colorado, Wyoming, Utah, and New England.

In Clayton Valley, located in Esmeralda County, Nevada, lithium-bearing brines occur in an undrained structural depression filled with Quaternary sediments composed mainly of clay minerals, including hectorite, volcanic sands, alluvial gravels, and saline minerals consisting of gypsum and halite (Kunasz, 1970).

In Clayton Valley, located in Esmeralda County, NV, lithium-bearing brines occur in an undrained structural depression filled with Quaternary sediments composed mainly of clay minerals, including hectorite, volcanic sands,

alluvial gravels, and saline minerals consisting of gypsum and halite (Kunasz, 1970).

The brine which saturates the sediments is chemically simple. It occurs as a concentrated sodium chloride solution containing subordinate amounts of potassium and minor amounts of magnesium and calcium. The lithium concentration is variable; the composite average pumped into the ponds is 200 ppm Li.

Zimbabwe

The largest lithium-bearing area in Zimbabwe is that of the Bikita tinfields, located about 72 km (45 miles) east of Fort Victoria. Exploration has indicated the presence of an important mineralized zone within the Al Hayat, Bikita, and Southern sectors. The pegmatite is about 1.6 km (5100 ft) long and its width varies from 29 to 64 m (95 to 210 ft). It strikes north-northeast and dips from 14° to 45° east.

The pegmatite is asymmetrically zoned and contains a variety of commercially important lithium minerals as well as beryl and pollucite.

Drilling and development work have proved a reserve of 12 million tons of quarry ore grading 1.4% Li. Mining is presently done in the Al Hayat sector.

Other minor lithium-bearing occurrences are known in the Wankie, Salisbury, Umtali, Mtoko, Insizua, Matobo, and Mazoe districts (Toombs, 1962).

MINOR PRODUCING DISTRICTS

South America

Only two countries produce small amounts of lithium minerals in South America: Brazil and Argentina. The amblygonite deposit in Surinam has been essentially depleted.

In Brazil, lithium-bearing pegmatites are known in the districts of Minas Gerais and in the northeastern portion of the country which includes the states of Paraíba, Rio Grande do Norte, and Ceará (Heinrich, 1964).

The pegmatites which carry spodumene and amblygonite usually have been mined for cassiterite, tantalite, and beryl, while the lithium minerals have been sporadically recovered as byproducts.

An important occurrence of petalite has been reported in the tin-producing district near Araçuaí, Brazil, located about 402 km (250 miles) northeast of Belo Horizonte in the state of Minas Gerais. The pegmatite is reported to contain about 100,000 tons of petalite grading 2.0% Li.

Spodumene reserves have been estimated at 300,000 tons, while lepidolite reserves are considered to be nearly exhausted.

In Argentina, lithium-bearing pegmatites occur in the western portion of the state in the Sierras Pampaneas, which include the productive districts of San Luis, Córdoba, and Catamarca. The pegmatites are zoned and contain spodumene. The reserves, considered to be small, total about 18,000 tons as spodumene (Angelleli and Rinaldi, 1963, 1965). Recently, the occurrence of brine has been reported in the salares of northwestern Argentina.

Namibia

Following a low production period, mining in the Karibib district was stimulated by the trade sanctions imposed on Southern Rhodesia (now Zimbabwe) in 1964. The district, located approximately 193 km (120 miles) from Walvis Bay on the Atlantic Ocean, contains several strongly zoned pegmatites which contain lepidolite, petalite, and small amounts of amblygonite.

Other African Deposits

In Africa, smaller productive areas occur in Mozambique, Uganda, and Ruanda.

In the Alto Ligonha area of Mozambique, lepidolite, amblygonite, and spodumene occur in zoned pegmatite bodies. Only lepidolite is exploited commercially. Amblygonite is rare, and spodumene is completely altered to kaolinite (Hutchinson and Claus, 1956).

Large amblygonite masses are found in pegmatite districts located west of the capital city of Kigali, in Ruanda (Valarmoff, 1954), and north of Kampala in Uganda (Roberts, 1948).

Other occurrences of lithium minerals include the Sudan, the Malagasy Republic, the Ivory Coast, and the Republic of South Africa (Nel, 1968).

Australia

The most important lithium-bearing districts occur in Western Australia. Mining is active only in the Coolgardie district where small quantities of petalite and minor amounts of spodumene and amblygonite are produced at London-derry. In the same area near Mt. Marion, the Western Mining Corp. has discovered a spodumene deposit. Drilling has indicated reserves in excess of 1,000,000 tons of ore (Anon., 1968).

Other lithium mineral occurrences include spodumene near Ravensthorpe, lepidolite near Wodgina and London-derry, and minor amblygonite near Euriovie, New South Wales (McLeod, 1965).

In addition to the producing areas described above, lithium minerals are known to occur in many European countries and in Ireland, India, Korea, and Japan. Sizeable deposits exist in the Soviet Union but actual reserves data are not available.

13. Magnesite

OSCAR M. WICKEN

Magnesite (MgCO_3) when pure has a composition of 47.8% MgO and 52.2% CO_2 . The pure mineral is sometimes, but rarely, found as transparent crystals resembling calcite, but most often it contains variable amounts of the carbonates, oxides, and silicates of iron; calcium; manganese; and aluminum in solid solution or as separate mineral entities.

Magnesite is one of the calcite group of rhombohedral carbonates that includes calcite (CaCO_3), siderite (FeCO_3), and rhodochrosite (MnCO_3) among others. The members of this group can enter into a wide range of substitutional solid solutions when the positive ions have similar radii. The radii of magnesium and iron ions are within 6% of each other; hence magnesite and siderite can form a complete series in which breunnerite (ferroan magnesite) is a well-known commercially valuable member. In contrast, the radius of the calcium ion is 36% larger than that of the magnesium ion, and only limited solution exists at each end of the MgCO_3 - CaCO_3 series. Dolomite is not a member of the calcite group, but results when calcium and magnesium ions alternate in equal numbers in an ordered structure among carbonate ions. The result of these relationships is that calcite and dolomite often found intermixed with magnesite as identifiable crystal entities can be separated to varying degrees from the magnesite by beneficiation techniques.

Magnesite may be either macrocrystalline or cryptocrystalline (amorphous). The macrocrystalline form has a hardness of 3.5 to 4.0 on Mohs' scale. The specific gravity of the pure mineral is 3.02, but often the presence of iron carbonate in solid solution raises the value. The color may range from white to black with hues of yellow, blue, red, or gray. The color is not a significant indicator of composition, but in a given deposit an experienced person can often roughly grade magnesite by assessing color and crystallinity.

Cryptocrystalline magnesite is massive with no cleavage. The fracture is conchoidal; hardness is 3.5 to 5.0. The color is normally white but it can display tints of yellow, orange, of buff. Sometimes it is descriptively called "bone magnesite." The specific gravity ranges around 2.8 to 3.0 depending on accessory mineral inclusions.

The macrocrystalline form occurs in relatively few but large deposits, whereas the cryptocrystalline variety tends to occur in many but relatively small deposits.

Essentially all mined magnesite is dead-burned or calcined to make a variety of grades of refractory or caustic magnesiases. Invariably provisions for some degree of beneficiation of the mined ore are required. The beneficiation steps may range from simple hand-sorting and scrubbing to more complex gravity, optical, and flotation methods to separate waste from the magnesite. However, occasionally some large deposits of macrocrystalline magnesite have blocks of sufficient purity to allow mining followed by direct firing of crushed and sized ore without other treatment. In any case, for most uses as a refractory material, the dead-burned product should contain at least 90% MgO; many commercial grades contain in excess of 95% MgO.

For uses as caustic magnesia in nonrefractory applications, the MgO content is often less important than other characteristics. Thus, magnesia contents of commercial grades can range downward to under 70% MgO and still be useful for certain applications.

ORIGIN, CHARACTERISTICS, AND EVALUATIONS OF DEPOSITS

Deposits of macro- and microcrystalline magnesite have practically no common features with each other as to origin, geologic structure, host rock, nor size. Each has its own unique features that dictate certain geologic study and exploration techniques. However, the mining and processing methods do have some common aspects in many cases.

Macrocrystalline Magnesite

The deposits are usually found in dolomitic terranes which can have areas measured in kilometers (square miles) and depths in hundreds of meters (feet). The magnesite itself occurs in the host structure as lenses and layers with horizontal dimensions that may be on the order of thousands of feet and depths of hundreds.

A variation in the magnesite-host rock relationship is seen in a deposit in Brazil where the magnesite is in a limestone measure (Bodenlos, 1954); however, even in this case the magnesite is not in direct contact with the limestone but is separated from it by a dolomitized zone.

Major deposits of macrocrystalline magnesite are found in Austria, Czechoslovakia, North Korea, China, Brazil, Canada, Nepal, and the United States. All are in dolomite host measures or zones. All are in regions of orogenic activity. Commonly such areas also show igneous activity, and an early and strongly supported theory postulated that magnesite resulted from the action of igneous intrusions and associated solutions on the dolomite (Wicken, Duncan, 1975). The dolomite measures themselves are widely viewed as sedimentary measures in which secondary placement of magnesite was brought about by hydrothermal action (Bain, 1924; Nishihara, 1956).

Deposits of this form of magnesite tend to be massive and physically homogenous. The magnesite formations are generally more resistant to weathering than associated formations; consequently, bold outcrops are characteristic of these deposits.

Exploration and Evaluation of Deposits: Outcrops are sampled by surface chipping and shallow trenching. Early evaluations of deposits are obtained by field mapping and from chemical and mineralogical analysis of samples to determine the quantity and distribution of accessory minerals containing silica, lime, iron oxide, and alumina. Tests to learn whether these undesirable minerals can be removed by ore dressing methods may be required as an aid to evaluation.

Following the preliminary surface investigations, a first-order drilling program would be carried out to assess the gross dimensions and the commercial potential of the deposit. Field mapping using standard techniques would be elaborated early by preparation of detailed maps showing surface configurations, geologic anomalies and features, and location of sampled sites and drill holes (Peters, 1978).

The drill-hole cuttings or cores are logged to show chemical and mineral features through the depth of the boreholes. The information from these first, widely spaced holes would be plotted to show cross sections of the deposit. Subsequent additional drilling would yield information to fill in the cross sections. At some point it may become desirable to log all

the drill-hole results into a computer data bank, particularly if the deposit shows substantial variation in thickness and composition at different levels. Graphic presentations would then be readily available to guide further exploration and subsequent mining operations (Carew, 1987).

Cryptocrystalline Magnesite

Deposits are found in contact with or close proximity to serpentinized ultrabasic rock structures. The magnesite results as an alteration product of serpentine or allied magnesian rocks which have been subjected to the action of hydrothermal solutions and surface carbonate waters. The serpentine, which lies near or surrounds the magnesite, is itself an alteration product of ultrabasic rock. The relationship between temperature and carbon dioxide pressure is critical for the formation of the magnesite. The zones near or at the earth's surface are most favorably situated for the reactions. Hence, deposits of cryptocrystalline magnesite are found near the surface and have limited and decreasing extent in depth.

Major deposits of cryptocrystalline magnesite are found in Yugoslavia, Greece, Australia, India, South Africa, Zimbabwe, Turkey, Baja California, Colombia, and Central America.

Deposits of cryptocrystalline magnesite occur in three different modes. In one, the magnesite is found in large or small quantities in stockwork structures of serpentinized ultrabasic rock. The magnesite occurs with erratic dimensions from less than a centimeter (inch) to several meters (feet).

A second pattern is revealed, for example, by those deposits in Turkey and Yugoslavia. The deposits in Turkey are well-defined single or parallel veins more or less vertically dipping. The veins may be several meters (feet) thick with undulating horizontal continuity of hundreds of meters (feet). The deposits in Yugoslavia are similar but are more deeply buried. In both cases, the deposits are hydrothermal formations.

In a third pattern, magnesite is found as lacustrine deposits of nodules or concretions laid down in mud sediments in lakes and shallow embayments, or, as in the case of the Salda Lake deposit in Turkey, directly on the banks of the lake (Schmid, 1987). The nodules in all cases are secondary, hydraulically transported, and reworked mineral forms which have precipitated from solutions derived from the weathering of magnesian stockwork in nearby serpentinized ultrabasic rock formations. The nodules can range in size from fine gravel up to boulders 1 m (3 ft) or more in diameter (Frost, 1987).

Exploration and Evaluation of Deposits: Stockwork structures of magnesite and ultrabasic rock are found characteristically as pronounced outcrops. The nearly white magnesite is easily seen against the dark gangue. In fact, beneficiation by optical methods is possible because of the color differences.

The outcrops are initially sampled by taking surface chip samples. These samples are useful for field and chemical tests to verify the presence of magnesite, establish the nature of associated rocks, and to give a first appraisal of the extent and dimensions of the deposit. However, in contrast to the information obtained from taking chip samples of macrocrystalline deposits, samples of stockwork structures yield little or no information as to the continuity and quantity of the magnesite. Also, in contrast to drilling for the evaluation of macrocrystalline magnesite deposits, a drilling program in stockwork has no early value. The important exploration of such exposures is by shallow trenching to observe the relative abundance, size, and continuity of veins and lenses.

Following favorable surface showings, adits may be driven to carry the exploration underground. At a certain point in the exploration program, large bulk samples should be taken for sorting tests to give information concerning the ratio of gangue to magnesite.

Magnesite deposits in vein structures are sampled by trenching along open exposures and by drilling following a program similar to that for macrocrystalline deposits.

In contrast to stockwork and vein deposits, both of which are found as outcrops, deposits of nodular magnesite often give no surface manifestation as the deposits may be covered with soil several meters (feet) thick. These lacustrine deposits—with or without soil cover—are evaluated in a program of excavating and drilling test pits and large diameter boreholes to determine the areal extent of the deposit, thicknesses of the nodule and overburden layers, and to provide samples for characterization of the nodules.

MINING PRACTICES

Depending on many circumstances such as anticipated reserves, kind of ore body, overburden, and ecological factors among others, mining can be by underground or by open pit methods or by a combination.

Underground Mining

The method has been used to some extent in the early development of many magnesite mines, particularly those that have had an operating history dating back several decades. Although the method has been largely abandoned elsewhere, it still survives in such places as, for example, Austria and Yugoslavia where the mountainous topography and thick rock overburden makes surface mining untenable. Where practiced, underground methods in large ore bodies are similar to those used in underground limestone operations; i.e., room and pillar patterns are developed, and the ore is removed by use of power loaders and trucks.

Open Pit Mining

This method is preponderately favored for ore removal. Stripping of overburden, the establishment of benches, and patterns of selective ore removal are guided by the information obtained from exploration and mapping programs. Stripping and ore removal are carried out with power shovels, trucks, scrapers, and front-end loaders. In the case of macrocrystalline deposits, the ratios of waste and overburden to ore are generally moderate as, for example, in Liaoning province of China some mines have ratios of 2.5:1 (Schmid, 1984); in the former operation of Northwest Magnesite Co. in Chewelah, WA, the ratio in the Red Marble deposit was 2.3:1. In the case of some stockwork deposits in Greece, the ratio sometimes exceeds 100:1. A modified form of open pit mining is found in Turkey where vertical vein deposits of cryptocrystalline magnesite are mined in open trench patterns on narrow benches.

The nodular forms of cryptocrystalline magnesite present entirely different recovery problems. As exemplified in the Australian deposits, the magnesite is not found as part of a rock formation, but as an unconsolidated layer of nodules under a shallow soil overburden a few meters (feet) thick. The strata of nodule concentration have variable thicknesses ranging from a few to several meters (feet). The concentrations and distribution of the nodules within the matrix of clay and miscellaneous silica, iron, calcium, and magnesium minerals are variable and unpredictable. Essentially, the overburden is stripped and the nodule layer is excavated using suitable earth-moving equipment. The magnesite is separated

from the matrix by screening and scrubbing. Published information (Schmid, 1987) indicates a ratio of overburden and matrix to nodules, although highly variable, to be on the order of 3:1.

PRACTICAL ASPECTS OF EXPLORATION

Exploration today for magnesite focuses almost exclusively on finding extensions to known deposits. The extensions need not closely adjoin the existing deposit but can be separated from it by miles of barren ground. The key condition is that the extensions are in the same geologic horizon and structure as the known deposit.

Little or no planned exploration for magnesite is carried out in totally virgin fields. From time to time, an occurrence of magnesite may be noted in virgin fields by an observant individual, but such accidental discoveries rarely, or slowly at best, lead to the development of a profitable mine. Economic factors weigh against the activity.

Parties seeking other minerals have sometimes found magnesite in the course of exploration; for example, a search for tungsten mineralization in Nevada led to the discovery of the Gabbs deposit (Vitaliano, 1957).

The decision to explore a favorable site calls for a substantial amount of support information developed in an exploration program. Briefly put, the program must be designed to show objectives, to indicate estimated costs and benefits, to provide an appraisal of the regional situations, and to outline the scope and plans for reconnaissance.

The objectives of the exploration would be to locate a magnesite deposit at reasonable cost that could be developed into a profitable operation. The reasons for the search might be protective to assure adequate magnesite for continuing or future exploitation to meet market demands, to establish a position as insurance against interruption of supply from current suppliers, or to enter a new field of activity in industrial minerals. The costs and benefits would be analyzed and detailed for each option.

Appraisal of the regional situation would cover such matters as property ownership, exploration and mining rights, leasing, royalties, taxation, labor, political aspects, and environmental parameters.

The reconnaissance activity should deliver as much geologic information as is available from all sources; obtain local and areal maps showing topography, known deposits, and areas to be explored; and gather information about climate, rainfall, drainage, and vegetation.

Pertinent information about different areas in the world is available from a number of agencies. Government bureaus, foreign embassies, the United Nations, for example, are useful

sources. Guides to information sources are available in many publications (Peters, 1978; Hoy, 1983). These and similar listings should be consulted as a prelude to serious exploration.

14. Manganese*

In 1774 a Swedish chemist, C. W. Schule, first recognized manganese as an element. That same year Schule's associate, J. G. Gahn, isolated the element manganese for the first time. In 1856 the Bessemer process of steelmaking gave birth to the economic importance of manganese. Later, in 1882, Robert Hadfield discovered high manganese steels.

Although the primary use of manganese is in the ferroalloy industry, two additional important uses for manganese are making chemicals and dry cell batteries. Manganese is also vital to plant and animal life. Various chemical compounds of manganese are used in fertilizers, feeds, glass manufacture, paints, varnishes, and for numerous medicinal and chemical purposes.

Although currently the world's largest consumer of manganese, the United States is producing only minor amounts of ore at the present time. This is due primarily to the fact that although huge deposits of manganese occur within US borders, all are of such low grade as to be economically unfeasible to mine.

For many years various government agencies and segments of private industry have devoted sizable sums of money and time in an attempt to upgrade ores from the various deposits, and also in an attempt to recover manganese from blast furnace slags. In view of current world prices, and the quantity of high grade material available, there is little likelihood that any of these approaches will be found to be economically feasible in the near future.

GEOLOGY AND MINERALOGY

Mineralogy

There are over one hundred minerals that contain manganese. These minerals vary from those with compositions that are predominantly manganese to those having only minor percentages:

Mineral	Chemical Composition	%Mn
Hausmannite	Mn_2O_4	72
Polianite	MnO_2	63.1
Pyrolusite	MnO_2	60-63
Cryptomelane	$KR_xO_{16}R$ (R=Mn)	Variable
Psilomelane	$Ba Mn Mn_8O_{16} (OH)_4$	45-60
Coronadite	$Pb R_8O_{16}R$ (R=Mn)	Variable
Hollandite	$Ba R_8O_{16}R$ (R=Mn)	Variable
Manganite	$Mn_2O_3 \cdot H_2O$	62
Braunite	$3 Mn_2O_3 \cdot MnSiO_3$	62
Tephroite	$2 MnO \cdot SiO_2$	54.3
Rhodochrosite	$MnCO_3$	47
Rhodonite	$MnSiO_3$	42
Spessartite	$3 MnO \cdot Al_2O_3 \cdot 3SiO_2$	33.3
Wad	Hydrous Mn Oxides	Variable
Franklinite	$(Fe Mn Zn)O(Fe Mn)_2O_3$	Variable
Asbolan	Cobaltiferous wad	Variable
Alabandite	MnS	63.14

*Excerpt from Jacoby, C.H., 1983, "Manganese," *Industrial Minerals and Rocks*, 5th ed., Vol. 2, S.J. Lefond, ed., AIME, NY, pp. 897-908.

Geology

From a geological standpoint, most manganese deposits are complex. In general, it can be said that all primary deposits of manganese are carbonates or silicates. The most productive and profitable have been those of sedimentary origin and residual concentrations. Examples of these residual types of deposits are associated with the metamorphosed lodes of Madhya Pradesh, India, and the lateritic deposits of Orissa and Bihar, India; nodules in the residual clays of the Philippine Islands, US southern Appalachians and Arkansas, Ghana, and Brazil.

Sedimentary manganese deposits are best exemplified by the Nikopol district of Russia and the Tchiatouri area of Georgia, USSR.

Hydrothermal replacements are characterized by the rhodochrosite deposits of Butte and Phillipsburg, MT. In general, the hydrothermal-type deposit has not resulted in any large tonnages being produced, but may have given rise to the formation of sedimentary deposits throughout geological history.

Some sedimentary and residual-type deposits have been metamorphosed, giving rise to small high-grade ore bodies. These deposits are regionally metamorphosed, occurring in marbles, slates, quartzites, schists, and gneisses. Some of these metamorphosed deposits, such as the Franklin, NJ, deposit, are rich enough to be commercial without secondary enrichment. However, most of the exploitable deposits have been secondarily enriched.

Manganese is widely distributed and, to a greater or lesser degree, replaces two sets of elements; first, alkaline earths, calcium, barium, and magnesium and, secondly, aluminum and iron. Due to the diversity and complexity of manganese deposits, both with respect to deposition and chemistry, a wide range of impurities is almost invariably present in the ores.

DISTRIBUTION OF DEPOSITS

Distribution of manganese deposits can best be described by the term "scattered." They vary from occurrences such as the nodules on the bottom of Lake Michigan at Green Bay to the bog ores of Wickes, MT; the rhodochrosite of Phillipsburg, MT; the franklinite of Franklin, NJ; to the residual pyrolusite deposits of Cartersville, GA. More than 2100 manganese deposits are listed in 35 states. Currently the free world's largest deposits of manganese ore are in Gabon, Brazil, Republic of South Africa, Ghana, and India.

Foreign Deposits

Principal reserves in foreign countries are as follows:

	Million Tons of Mn
USSR	Unknown-in excess of 200
Republic of South Africa	300
Gabon	96
Brazil	46
Australia	44
India	22
World reserves, total	700

Russia possesses what are probably the world's two largest manganese deposits. The largest of these is the flat-lying Eocene deposit at Tchiatouri in Georgia, south of the Cau-

casus Mountains. These are beds of oolitic pyrolusite interbedded with layers of clays, sandstones, and marls. Upon beneficiation, primarily washing, these ores produce concentrates containing 50% MnO_2 , and from 1 to 2% iron. The second great deposit of Russia lies in the Nikopol District on the Dnieper River in the Ukraine. Again, these are flat-lying beds close to the surface and easily accessible to strip mining. The beds of pyrolusite are interbedded with sand and glauconitic clays. These beds of Oligocene age rest on crystalline rocks covering approximately 415 km^2 (160 sq miles).

US Deposits

The largest deposit, or at least one of the largest, in the United States is located at Chamberlain, SD. This deposit is sedimentary in origin and consists of manganiferous concretions in the Pierre shale which is Upper Carboniferous in age. This formation varies in thickness from a few meters to 11.6 m (few feet to 38 ft) at Chamberlain.

The Batesville, AR, deposit contains a sporadic scattering of pyrolusite and wad-type residual materials in clay. Also buttons and thin layers of oxides are found in the Cason shale. This deposit rests on a fine-grained weathered limestone which gives rise to pinnacles, precluding the use of normal strip mining operations.

The Cuyuna iron range in Minnesota contains iron ore carrying varying quantities of manganese. The manganese content ranges from less than 1% to more than 17%. The manganese was originally sedimentary in origin but has undergone some secondary deposition in the filling of fractures and crevices.

Southern Appalachian deposits begin in the area of the Shenandoah Valley and extend south to the area of Cartersville, GA, and on into Alabama. While a wide variety of manganese minerals occur in lenses, beds, and residual pockets, only the oxides in residual pockets have been of any economic importance. In Virginia these occur as a series of small deposits extending for 129 km (80 miles) along the foot of the Blue Ridge Mountains. In general, most of the mines which have produced in excess of one million tons of manganese concentrates have been small operations conducted by local operators. Exceptions to this are the Crimora mine, working residual layers and pockets in the Erwin sandstone and the Kendall and Flick mines. These deposits, which have proven of economic importance, are the result of deep weathering. While the geological features of the primary deposits are undoubtedly dissimilar, the secondary residual deposits have many similarities.

The deposit at Artillery Mountains in Arizona has been operated from time to time during national emergencies. It has been estimated that the deposit contains approximately 159 Mt (175 million tons) of ore averaging from 3 to 4% manganese, with zones of material carrying values as high as 20% manganese. Beneficiation studies have made concentrates from which ferromanganese has been produced. The average iron content of these stratified oxides is 3% with 0.08% phosphorous.

The Three Kids property near Henderson, NV, was operated by Manganese, Inc. during World War II. At that time it was the largest producer of manganese in the United States. The primary ore, containing about 18% manganese, was beneficiated to produce a concentrate averaging 45% manganese.

Numerous other districts supply varying quantities of manganese during times of national emergency and stockpiling. The Anaconda Co. has produced approximately 1.8

Mkg (4 million lb) of manganese from the Butte District in Montana. Manganese, zinc, and silver have been deposited in the peripheral zone as rhodochrosite and manganosiderite. Almost all of the production has come from the mining of rhodochrosite. The Emma mine, located in the southernmost Anaconda vein, mined the "great bulge" at the east end. The Phillipsburg District gave rise to manganese, silver, lead, and zinc as replacement veins in limestones and shales. In part, the rhodochrosite of these deposits has been altered with the formation of high grade oxides. The primary source of the manganese was the Granite-Bimetallic vein, which produced silver and gold.

Aroostook County, ME, contains large reserves of manganese mixed with iron in a 1 to 2 ratio. The ore is a mixture of fine grained minerals including silicates and carbonates. These bedded deposits are steeply dipping slates which have been folded and faulted. Over 40 deposits are known to exist in an area 145 km (90 miles) long by 48 km (30 miles) wide.

Manganese Nodules on the Ocean Floors

The occurrence of large tonnages of manganese nodules in the three major oceans has been well established. Cardwell (1973) gives detailed chemical analyses for nodules taken from 54 different Pacific Ocean locations. The two major elements are manganese and iron. The minimal manganese analyses averaged 8.2% Mn, the maximum 50.1% Mn, and a median value of 24.2% Mn was determined. The percent nickel values on the same samples were 0.16%, 2.0%, and 0.99%, respectively.

The three manganese minerals found were todorokite, birnesite, and delta manganese dioxide. Todorokite varies in its chemical composition and can contain significant amounts of other elements substituted for manganese in the crystal lattice. It is basically a calcium, sodium, manganese, potassium, and magnesium oxide with three molecules of water. Birnesite contains less lattice substituted elements and has the typical formula:

These three forms of manganese show the degrees of oxidation increasing from todorokite, through birnesite, to delta manganese dioxide. The only iron mineral which has been recognized in the nodules is goethite.

Archer (1973) in reviewing the progress and prospects of marine mining estimates that a commercial manganese nodule mining operation would operate at a rate between 0.9 and 2.7 Mt (1 and 3 million stpy) (dry weights). Allowing for processing losses, a 0.9-Mt (1 million-stpy) operation is likely to be capable of providing about 11.8 kt (13,000 tons) of nickel, 10 kt (11,000 tons) of copper, 2.3 kt (2500 tons) of cobalt, and 245 kt (270,000 tons) of manganese. It is highly probable that manganese and cobalt will be considered byproducts with the scale of mining depending mostly on the world demand for nickel.

EXPLORATION AND EVALUATION

Manganese deposits are one of the more difficult ores to evaluate. In general, the deposits are small and scattered and expensive geophysical means are not usually economically feasible. Also the geophysical exploration costs are often beyond the financial capacity of the small operator. However, since manganese has relatively high solubility, geochemical techniques can be an effective tool in an exploration program.

One of the main difficulties is securing representative samples of an ore body for proper evaluation and analysis. In the past, a large percentage of the holes drilled for samples

were by cable or churn drill methods. These methods require extreme care in order to secure valid data. In most cases the data have been inaccurate.

Rotary drilling techniques are somewhat better, but again, extreme care must be exercised in order to secure representative samples. Where the deposit contains wad or soft oxides in clay, soil sampling methods can be used. Generally, where residual or detritus has occurred in a clay, the particle size of the manganese mineralization ranges from large boulders to $-75\ \mu\text{m}$ (-200 mesh) material. This makes soil sampling procedures difficult to employ.

In general the hard and deeper deposits are easier to sample with some degree of accuracy.

Although a great many manganese occurrences are known, the limited size of many of these deposits make them marginal to submarginal. Other large deposits are not economically exploitable due to the low concentration of manganese. The third consideration, and of prime importance, are the impurities associated with the manganese mineralization.

Due to the diversity and complexity of manganese formations, the impurities are many in number and complex in nature. Following is a broad generalization of the types of impurities:

- 1) Metallic impurities: iron, lead, zinc, copper, arsenic, and silver minerals.
- 2) Nonmetallic impurities: sulfur and phosphorous minerals.
- 3) Gangue: silica, alumina, lime, magnesia, and barium.
- 4) Volatiles: water, carbon dioxide, and organic matters.

Primary factors in the evaluation of deposits within the United States are the amenability of the material to beneficiation, and the price projection over the life of the necessary capital investment. Considerable effort has gone into the upgrading of ores from the various larger deposits within the continental limits of the United States.

Prior to World War II, few manganese operations had milling plants which were more complicated than washing, screening, jigs, tables, and, in a few instances, flotation. Now it is not only necessary to increase the manganese content, but also to decrease the percentage of impurities. Because each deposit is distinctly different from most other deposits, no single process is applicable to all.

15. Mica*

Mica is a platy mineral occurring in a variety of complex hydrous aluminosilicate forms with differing chemical composition and physical properties. Principal minerals in the mica group include:

- Muscovite—potassium mica (colorless or pale green/ruby)
- Phlogopite—magnesium mica (dark brown or amber)
- Biotite—magnesium-iron mica (black or dark green)
- Lepidolite—lithium mica (lilac)

Selected properties are given in Table 1. Muscovite is most important commercially with phlogopite of lesser use. The laminated structure of mica enables it to be split into very thin films which are transparent and tough as well as having outstanding dielectric and insulating properties.

Commercially, mica is used in a number of forms (Chowdbury, 1941; Rajgarhia, 1951; Skow, 1962). *Sheet mica* consists of flat sheets mined from naturally occurring books of mica, free from defects and capable of being punched or stamped into required shapes. Sheet mica is separately classified into *blocks*, *films*, or *splittings* according to thickness.

Built-up mica, or *micanite*, is made by arranging overlapping splittings in layers cemented with a binder and pressed together at high temperature.

Reconstituted mica, or *mica paper*, is made by depositing fine flakes of high-quality scrap mica in a continuous film impregnated with binder.

Scrap and *flake mica* are normally unsuitable in quality or size for making sheet mica. Originally the term *scrap mica* referred to the waste byproduct of mining and fabricating sheet mica, and distinct uses were developed for this material. Subsequently it became economically feasible to mine lower quality mica for these uses, and the term *flake mica* was introduced. Although the two terms are still used somewhat synonymously, it is considered better, at least in the United

States, to use the term *flake mica* in referring to mica mined for uses other than as sheet mica; and to restrict the term *scrap mica* to mica mined for or with sheet mica, but which will not meet the specifications.

Synthetic mica, such as fluorophlogopite, is produced by slow crystallization of a melted blend of pure raw materials.

MINERALOGY

In the true sense the term *mica* does not relate to a particular mineral, but to a group or family of minerals of similar chemical composition and to some extent similar physical properties. These minerals are predominantly potassium aluminum silicates with varying amounts of magnesium, iron, and lithium. The precise formulas and isomorphic relationships of the various group members have been studied, but general agreement has not been reached (Grimshaw, 1971; Hurlbut, 1952; Skow, 1962). The general formula describing the chemical composition of micas is

where X is mainly K, Na, or Ca; Y is mainly Al, Mg, or Fe; and Z is mainly Si or Al (Deer, et al., 1962).

These minerals have an internal structure of the layered lattice type where the silicon atoms are in the center of a tetrahedral grouping of oxygen atoms. The groups are linked together in a single plane by three oxygen atoms that lie within the common plane. Each of these oxygen atoms is shared by two tetrahedra. These linked tetrahedral groups, when continually extended, produce a hexagonal network within the plane. This internal structure of the mica has been used to explain the external pseudohexagonal structure of a mica crystal. When a pair of silicon-oxygen sheets that have had about one-fourth of the silicon atoms replaced by aluminum to form a mica are oriented with the tetrahedra vertices pointing at each other, a firm double-layered structure is formed with hydroxyl groups and metallic atoms such as aluminum, magnesium, and lithium between them. These double-layered structures are joined together by potassium atoms. The cleavage plane of the mica is found between these double-layered structures.

Table 1—Selected Properties of Various Micas

Chemical Constituent	Muscovite	Phlogopite	Biotite
SiO ₂	46	40	37
Al ₂ O ₃	35	17	18
K ₂ O	10.5	10	9
MgO	0.5	26	8
Fe ₂ O ₃	1	0.2	2
FeO	1	2.8	21
Na ₂ O	1	0.5	1
Minor	0.5	0.5	1
H ₂ O	4.5	3	3
Total	100	100	100
Specific gravity	2.77-2.88	2.76-2.90	2.70-3.30
Mohs' hardness	2½-3	2-2½	2½-4
Optic axial angle	30°-47°	0-15°	0-25°
Temp. of decomposition	400-500°C	850-1000°C	
Dielectric constant	6.5-9.0	5.0-6.0	
Specific heat, 25°C	0.206-0.209	0.206-0.209	

*Excerpt from Chapman, G.P., 1983, "Mica," *Industrial Minerals and Rocks*, 5th ed., Vol. 2, S.J. Lefond, ed., AIME, New York, pp. 915-929.

In addition to the better known members of the mica group—muscovite, phlogopite, biotite, lepidolite—there are zinnwaldite, a lithium-iron mica, fuchsite, a chromium mica, and roscoelite, a vanadium mica. Of the known micas, only muscovite and phlogopite exhibit any large commercial demand.

These micas crystallize in the monoclinic system with crystals that usually form in hexagonal or rhomb-shaped scales, prisms, or plates, with plane angles on the base of about 60° or 120°. The crystal faces are rarely smooth or well defined except for the basal plane. When a mica cleavage plate is struck sharply by a blunt needle, a six-rayed percussion figure is formed. The figure's most prominent line is parallel to the crystal's plane of symmetry; the remaining two lines are almost parallel to the crystal's prismatic edges. The percussion figure, in conjunction with the position of the optic axes as seen in an interference figure under the polarizing microscope, is useful in making a quick distinction between muscovite and phlogopite, which may closely resemble each other visually. Phlogopite, like biotite, has the plane of the optic axes parallel with the plane of symmetry of the crystal; muscovite has the plane of the optic axes perpendicular to the plane of symmetry. (When a blunt punch is pressed on a mica cleavage plate, a pressure figure is produced. The lines of the pressure figure are perpendicular to those of the percussion figure, but the pressure figure generally develops only partially.)

Minerals of the mica group have the distinctive physical property of being both flexible and elastic. On this basis they are readily distinguished from chlorite, talc, and vermiculite, flakes which will readily bend but will not snap back to their original position when released.

Muscovite has excellent basal cleavage that allows it to be split into very thin sheets exhibiting a high degree of flexibility, elasticity, and toughness. Very thin sheets of clear muscovite are transparent and colorless or almost colorless. In thicker sheets, it can be translucent and exhibit light shades of yellow, brown, green, or red. The mineral is strongly birefringent and exhibits a feeble pleochroism unless it is dark colored. The material is optically negative. The axial angle varies from 30° to 47° and is dependent on variation in the material's composition. The optic axes lie in a plane that is normal to the crystal's plane symmetry. Upon heating, muscovite commences to lose water at about 500°C. Muscovite is decomposed only by hydrofluoric acid.

The utility and value of sheet mica depends on the freedom from certain physical defects that occur as a result of the environment and events that occurred during and after crystallization of the mica. These defects are structural imperfections of the cleavage surfaces due to mineral inclusions.

Some of the structural imperfections associated with mica are reeves or cross grains which are lines, striations, or sharp folds in the plane of cleavage; "A" structure, which usually consists of two sets of reeves intersecting on a cleavage surface at about 60°; herringbone structure formed by two sets of reeves intersecting at about 120° along a central line of reeves; wedge mica which consists of mica runs that are thicker at one end than the other; warping which causes a mica characterized by shallow waves or ridges; ruled mica which has regular, sharply defined parting planes that intersect the basal cleavage plane at about a 67° angle; and tangle-sheet mica which is formed by an intergrowth of parts of one mica crystal with another. Most of these defects preclude use of the mica as sheet mica but do not interfere with its use as flake mica.

Mineral inclusions in mica can also limit the utility of

sheet mica. These inclusions and intergrowths of other minerals are broadly classed as stains. Some mineral stains appear parallel with the cleavage, but others can penetrate the cleavage plane and cause pinholes. Examples of staining are those formed during mica crystallization and include mottling, inorganic stains, mineral inclusions, and intergrowths. Additional staining can be caused by the circulation of ground water. Mica deposits that have been stained will yield little usable sheet mica.

Phlogopite has a pearly to submetallic luster and varies from translucent to transparent in thin sheets. Phlogopite has been identified in colors ranging from brownish red through yellowish brown, greenish brown, and dark pearl grey to an almost colorless pale green. The color intensifies as the iron content of the mineral increases. Darker colored samples of this mineral exhibit greater hardness than those of lighter color. Phlogopite can contain fluorine which is usually most prominent in reddish brown samples and least in greenish specimens. Phlogopite generally exhibits a distinct pleochroism.

The mineral is optically negative and its optic axial angle varies from 0° to 15°, apparently increasing directly as a function of the iron content. The plane of the optic axes is parallel to the crystal's plane of symmetry. When heated, phlogopite will not dehydrate greatly until about 1000°C. The reaction to acids is variable. Hydrochloric acid will attack the mineral mildly. Hot concentrated sulfuric acid decomposes phlogopite completely.

HISTORICAL BACKGROUND

Sheet Mica

Evidence exists of the use of mica as far back as the earliest civilizations, especially in the Nile Valley and India prior to 2000 B.C.

One of the earliest uses of mica was as a medicine, and even today Hindu physicians use fused biotite. The lustre, iridescence and transparency of the larger sheets led to applications as windows, mirrors, adornments, and plates for painting mythological scenes and the like. The American Indians of the southern Appalachians are known to have used mica in ornamentation at grave sites in the 14th century.

The Romans were probably responsible for the name, from the Latin word *micare* meaning to shine or glitter. Pliny mentioned material scattered over the Circus Maximus to impart a shining whiteness, and window coverings of transparent stones; these may have been in reference to mica.

Muscovite probably derives from the Russian district of *Moscovia* where de Boodt found and identified potash mica in 1609. The Russians also used mica for medicine. Their men-of-war had mica portholes. Thin sheets of mica were used to protect the surface of icons from being kissed by worshippers.

Commercial mica mining was started in the United States in 1803 at the Ruggles Mines in Grafton County, NH. Primary uses of mica in the 1800s were for stove windows, shades for open-flame lights, and for furnace viewing glass. Although the United States originally was self-sufficient in its mica production, by 1885 India had become a major supplier of muscovite sheet.

The appearance of Thomas Edison's bipolar generator in 1878, his incandescent lamp in 1879, and his system of central-station power production in 1882 stimulated commercial development of electric power-generation.

Growth of the US electrical industry opened up many uses for sheet mica. Mica has proved to be the best insulation

for use in commutator segments of large electric generators and motors. The US electrical industry grew so fast that the domestic reserves of large sheets were rapidly depleted.

A patent was issued in 1892 for the first built-up mica that maintained the dielectric and mechanical properties of natural mica. The use of splittings for built-up mica further depleted US reserves and led to increased imports of Indian mica.

Mica was used as spacers and insulators in the diode vacuum tube developed in 1904, and in the triode which followed in 1906. The vacuum tube industry grew in importance with the outbreak of World War I, and large quantities of mica were required to support the war effort. Mica retained its importance in the interwar period through use in the radio industry as well as in the growing electrical industry.

During World War II mica demand was heightened by the great increase in sophisticated electronic gear. The United States worked with the United Kingdom to stimulate production in India and other mica-producing countries. After the war, sheet mica production dropped off dramatically and the decline continues in the 1980s, caused by the rapid advancement of solid-state electronics.

Ground Mica

In 1890 J.S. Williams of the Richmond Mica Co. in Virginia produced ground mica as an ingredient for axle greases. Soon afterward the Vance brothers installed the first chaser mill in North Carolina producing wet ground mica for pigments, to be followed by wet-grinding by Williams.

From there the American industry grew. In 1908 Thomas English formed the English Mica Co. in Spruce Pine, NC. In the 1920s J.B. Preston Co. bought English Mica and merged it with the Biotite Mica Co. and Roofing Mica Co. Franklin Mica Products was started by John Davenport in Franklin, NC. In New Hampshire, what is now Concord Mica Co. was formed by Earl Moore. Diamond Mica Co. and Hayden Mica Co. were formed after World War II.

In the 1930s wet ground mica production started in Derby, England, and some dry grinding production began in Europe and India. Micronized mica emerged in Norway

and England in the 1960s with further wet grinding plants in Norway, France, and South Africa.

The large growth in mica grinding came in dry ground mica from the 1940s onward, first with the uses in roofing felts and shingles in the US and, as that declined, with the emergence of drywall joint cements and oil-well lost circulation additives.

The 1970s saw the decline of water-grinding as rising energy costs made the products uneconomic and several plants in the US and Europe closed.

COUNTRIES OF ORIGIN

The most important countries producing mica are listed in Table 2, together with an estimate of their mica-scrap output. An attempt has been made to show how the total supply is distributed around the world for use in the manufacture of ground mica.

It will be seen that approximately 50% of the mica arises in the United States with four other countries—USSR, India, China, and Canada—making up the next 35%.

United States

Approximately 60% of US scrap is from North Carolina and consists of byproduct mica from the feldspar, kaolin, and lithium producers. Virtually all is ground in mills located near the mines. The remaining mica comes mainly from Alabama, Connecticut, Georgia, New Mexico, and South Carolina.

USSR

The pegmatite deposits of Karelia and Maura River regions appear to dominate production, but little information is published regarding mica-grinding. Apparently no exports are made outside Eastern Bloc countries.

India

High quality mica is mined in the United States of Bihar, Rajasthan, and Andhra Pradesh for sheet mica production, and the consequent scrap is exported for mica-paper manufacture or ground in India for home and overseas consumption.

Table 2 Countries of Origin and Consumption of Mica, t/a

Country of Origin as Raw Material	Eventual Consumption as Mica Powder or Flakes							Total
	US and Canada	USSR and Eastern Bloc	Europe	Far East and Australia	Middle East	Africa	South America and West Indies	
USA	105,000	500	2,500	1,000	200	300	500	110,000
USSR		35,000						35,000
India	1,000	7,000	3,000	5,000	4,000	1,000		21,000
China			8,000	4,000				12,000
Canada	12,000		1,500	1,500				15,000
Brazil	1,000		5,000				1,000	7,000
France			6,000					6,000
Spain			4,000					4,000
South Africa			1,500	500		1,000		3,000
Korea				3,000				3,000
Norway			2,000					2,000
Argentina			1,000				1,000	2,000
Italy			1,000					1,000
Others		1,000	1,000	1,000				3,000
European Re-exports	500	1,000	(4,000)	500	800	700	500	
Total	119,500	44,500	32,500	16,500	5,000	3,000	3,000	224,000

China

Mica is produced in a number of regions from pegmatite or as a feldspar byproduct. The most important area is Tientsin province.

Canada

Output consists of flake phlogopite mined in Quebec province and ground at a plant near Montreal. This is the only significant production of ground phlogopite on a world basis.

Madagascar

High quality phlogopite is mined for use as sheet mica to satisfy the electrical and mica paper markets of Europe and America.

GEOLOGIC FEATURES OF MICA DEPOSITS

Sheet Mica

Large crystals or books of muscovite and phlogopite mica are generally found in regionally metamorphosed rocks. Granitic pegmatites are the source of muscovite sheet. Phlogopite sheet is found in areas of metamorphosed sedimentary rocks into which pegmatite-rich granite rocks have intruded.

Pegmatites are generally the only source of usable quality sheet mica. Although there are many mica-bearing deposits throughout the world, only a few localities have deposits that are of economic importance. These pegmatites are light-colored, coarsely crystalline igneous rocks. They can be found as dikes or sills in metamorphic rocks and large granite intrusions. The mica crystals found in these deposits range from less than one inch to many feet in length. Variation of size within an individual deposit is not uncommon. Mica-bearing pegmatites have been known to exceed 61 m (200 ft) in thickness and 305 m (1000 ft) in length and have been worked to depths ranging from 61 to 152 m (200 to 500 ft). However, mica also has been produced from shallow surface deposits.

Pegmatites are composed primarily of feldspar, quartz, and mica. In many geologic situations accessory minerals such as garnet, tourmaline, and beryl occur with the primary pegmatite constituents. The distribution of minerals in pegmatites may be even, zoned, or segregated into layers.

Deposits of large books of phlogopite mica that can economically provide large quantities of sheet mica are available in only a few places. Skow (1962) has classified phlogopite deposits into vein, pocket, and contact deposits. Vein deposits, which are generally narrow and are enclosed in fine to medium grained pyroxenite, are the major source of phlogopite sheet mica. Pocket deposits have been found to be irregular in shape, size, course, and persistence. The surrounding pyroxenite of this type of deposit is usually more coarsely crystalline and open textured than that found with vein deposits. The phlogopite crystals may be irregularly distributed throughout the pocket along with crystals of other minerals such as pyroxene and calcite or may occur as very large solid masses of phlogopite.

Scrap and Flake Mica

Originally scrap mica was derived from the mining and processing of sheet mica and included poor quality sheet mica that did not meet the specifications for size, color, and quality. However, the industrial demand for scrap mica began to increase greatly in the 20th century, and mica deposits were mined specifically for the smaller size mica crystals or flake mica found in coarse-grained, weathered, granitic rocks such as alaskite and pegmatite, and in some schists. Flake

mica is also recovered as a coproduct from the production of clay, feldspar, and spodumene.

Technology has been developed that permits the recovery of small particle size flake mica from various mica-bearing sources such as mica schist, graphitic mica schist, granite, silt, and recovery plant tailings. Good recovery rates for mica have been reported by the use of grinding and flotation techniques.

EXPLORATION

Sheet Mica

Exploration for sheet mica is not amenable to most of the methodology used to search for other minerals. The sporadic occurrence of large runs of books of mica crystals in the host rock makes it uneconomic to drill a deposit to any great extent to determine the mica content. Any drilling that is done can only delineate the existence of pegmatite and may reveal very little information about the mica content.

Prospecting for sheet mica has failed to advance beyond the trial and error method. Geological evidence is generally insufficient to supply enough information for the evaluation of a deposit. The most practical prospecting method for sheet mica is to sink a test pit in an effort to determine the percentage, size, and quality of trimmed sheet that might be obtained from a deposit. A potential deposit may be stripped or trenched by mechanical or hand methods to outline the size, shape, and attitude of the pegmatite vein for the purpose of selecting the sites for test pits or to supplement the information obtained from test pits. A common method of further exploration for sheet mica consists of sinking a shaft either down dip in the pegmatite body or vertically to cut the pegmatite at the desired depth. Drifts can then be driven along the strike of the deposit in both directions. Any large mica crystals that are found are visually examined by experienced mica workers who determine their freedom from structural imperfection and their suitability for sale. Steeply dipping pegmatites can be explored by the construction of adits. As yet, geophysical and geochemical techniques have not been applied to prospect and evaluate deposits containing sheet mica. The search for mica sheet remains basically a pick and shovel operation with some limited usage of mechanized equipment.

Flake Mica

Small particle size flake mica that is distributed in deposits of pegmatite, schist, and clay can be evaluated by conventional methods. The location of a deposit can be determined from surface geology. If the surface outcrops are of sufficient size, surface sampling may be justified, but it is more likely that the deposit would be augered or drilled to a shallow depth to furnish samples for testing and delineation of the deposit.

Ore samples obtained in this manner are crushed to a range of sizes to determine the optimum crushing size at which the ore will release the maximum quantity of mica. Chemical analysis is not effective for mica determination because of the wide variation of the chemical composition of the various micas. Petrographic analysis is not completely satisfactory to evaluate the mica content of a sample. The mica industry has not established a standard method of analysis to determine the mica content of an ore sample.

Sink-float techniques can be applied to the crushed samples of pegmatites and schists to assess the capability of separating mica from its accessory minerals by the use of a heavy liquid such as tetrabromoethane or mixtures of tetra-

bromoethane and kerosene or trichloroethylene. Experiments can be carried out to determine if mica can be extracted from the ore sample by some method of flotation.

As a result of preliminary studies, a flowsheet for the recovery of mica can be developed and a small pilot operation erected to determine the feasibility of the method of recovery.

The final test of any flake mica is reached when it is ground and/or classified to a particular particle size and accepted for an industrial end use.

16. Natural Abrasives*

Abrasives include the substances that are used to grind, polish, abrade, scour, clean, or otherwise remove solid material, usually by rubbing action but also by impact (pressure blasting for example). They do not include abrasive tools, for instance, lathe tools and files—or polishing agents such as waxes, which act by filling pores.

Detergents and cleaners whose action is chemical rather than physical are omitted although some chemical-action polishes and cleaners may also contain solid abrasives, for example, many automobile and metal polishes.

GENERAL CONSIDERATIONS

The most important physical properties of materials that qualify them for use as abrasives are hardness, toughness (or brittleness), grain shape and size, character of fracture or cleavage, purity or uniformity. For making bonded abrasive products such as grinding wheels, additional important factors are stability under high heat and bonding characteristics of grain surfaces. The economic factors of cost and availability are always important.

No one single property is paramount for any use. For some uses extreme hardness and toughness are needed, as in diamonds for drill bits; for others, the factors of greatest importance are hardness and ability to break down slowly under use, to develop fresh cutting edges when grains become worn—for example: in garnet for sandpaper neither highly cleavable or friable grains nor extremely tough grains are wanted. For still other uses, great hardness is objectionable; for example, abrasives for dentifrices and for glass-cleaning soaps. For the most efficient use in the more critical applications, the different types of abrasives are rarely completely interchangeable; thus, while crushed quartz and garnet are both used in sandpaper, the papers are not at all interchangeable in their use applications.

In the last analysis, the choice of a high grade abrasive depends upon the quality and quantity of work done by the abrasive per unit of cost. Initial cost of an artificial abrasive may be much greater than that of a natural abrasive but the artificial abrasive may do so much better work than the natural one, and do it so much faster that the ultimate cost will be less. It is for this reason that artificial abrasives have largely replaced natural abrasives.

CLASSIFICATION

Abrasives may be divided into two general classes, natural and manufactured. The former includes all rocks and minerals used for abrasive purposes without chemical or physical change other than crushing, shaping, or bonding into suitable forms. Manufactured or artificial abrasives are made either by heat or chemical action from metals or mineral raw materials.

Table 1 lists most of the important abrasives, classified as to inherent types and the forms in which they are used industrially.

For most types of use there are manufactured products that can be substituted for the natural products, usually at higher initial cost but with higher efficiency. This is not

always true; for example, there is no satisfactory manufactured substitute for garnet for making coated abrasive paper and cloth. For some abrasives whose use is gradually lessening—for instance, chaser stones—the making of manufactured substitutes has not been economically attractive, but for even such a low-priced commodity as pressure blasting sand there are substitutes such as steel shot, fused aluminum oxide, and silicon carbide grains.

The decline in the use of most natural abrasives and their replacement by manufactured abrasives has not been a net loss to the mineral industry, however, for virtually all manufactured abrasives are made from mineral raw materials.

NATURAL ABRASIVES

Corundum and Emery

Corundum and emery have become of relatively little importance both from the standpoint of domestic production and consumption and on a worldwide basis. No corundum is mined today in the United States or Canada and there are only two relatively small producers of emery, both in the Peekskill, NY, area. At this locality, a spinel emery occurs in veins in an igneous complex of hornblende and olivine pyroxenite. It is associated with mica schist in rocks containing sillimanite, cordierite, garnet, and quartz. Most of the domestic emery is used in tumbling barrels and for various types of nonslip floors and stair treads. Production in recent years has come from two producers and has averaged about 9 kt/a (10,000 stpy) valued at about \$20 per ton.

Diamonds—Industrial

Their uses as abrasives are outlined here.

In 1981 the total world production of natural industrial diamonds of all types was about 31,100,000 carats, with US imports of 21,600,000 valued at \$5.34 per carat.

There are three major types of natural industrial diamonds: (1) bort, which includes off-color, flawed, or broken fragments of diamonds unsuitable for gems, (2) carbonado, or black diamond, which is a very hard and extremely tough aggregate of very small diamond crystals, and (3) ballas, a very hard, tough, globular mass of diamond crystals radiating from a common center. Carbonadoes come only from Bahia, Brazil; ballas chiefly from Brazil but a few from South Africa. Bort comes from all diamond-producing centers. In addition, there is a considerable production of diamond dust and powder, waste from cutting gem diamonds.

The industrial diamond has become one of the most important and essential materials in modern industry. Diamond drilling, once used only for locating metallic ores, is now widely used also for exploring nonmetallic mineral deposits; for exploring geologic structures; for testing foundations for dams, buildings, and heavy machinery; for exploring internal condition in heavy concrete structures such as dams; for stope mining; explosive demolitions under special conditions; and other purposes.

Some of the most important uses are: diamond-drill bits for drilling rock and concrete; diamond dies for wire drawings; diamond-tipped tools for truing abrasive wheels and for turning and boring hard rubber, fiber, vulcanite, hard plastics, etc.; diamond-toothed (segmental) saws and rim-impregnated (continuous rim) saws for sawing stone, glass, quartz, metals, slicing expansion joints in concrete highways, etc.; wheels, both for grinding and for cutoff work, in which

Table 1. Classification of Abrasives

<i>Natural Abrasives</i>	
Superior Hardness (above 7 in Mohs' scale)	
Diamond H-10	Calcium carbonate (pptd.)
Corundum H-9	Calcium phosphate
Emery H-7 to 9	Cerium oxide
Garnet H-6.5 to 7.5	Chromium oxide
Staurolite H-7.0 to 7.5	Clay (hard burned)
Intermediate Hardness (H-5.5 to 7)	Diamond
Silica Abrasives	Fused alumina
Buhrstone	Glass
Chalcedony	Iron oxides
Chert	Lampblack
Flint	Lime
Novaculite	Magnesia (pptd.)
Quartz	Manganese dioxide
Quartzite	Periclase (artif.)
Sandstone	Silicon carbide
Silica sand	Tantalum carbide
Other Rocks and Minerals	Tin oxide
Argillaceous limestone	Titanium carbide
Basalt	Tungsten carbide
Feldspar	Zirconium oxide
Granite	Zirconium silicate
Mica schist	
Perlite	Metallic abrasives, including steel wool, steel shot, angular steel grit, brass wool, and copper wool
Pumice and pumicite	Porcelain blocks for mill liners and grinding pebbles
Quartz conglomerate	
Inferior Hardness (H-under 5.5)	<i>Types of Abrasive Products</i>
Apatite	Abrasive grains and powders, loose
Calcite	Abrasive grains bonded into wheels, blocks, and special shapes
Chalk	Coated abrasives; grains bonded to paper and cloth
Clay	Abrasive grains and powders; paste form; oil or water vehicles
Diatomite	Abrasive grains and powders; brick and stick form; grease, glue, and wax binders
Dolomite	Natural rocks shaped into grindstones, pulpstones, chaser stones, millstones, etc.
Iron oxides	Natural rocks shaped into sharpening stones, such as oil stones, whetstones, scythe stones, razor hones, etc.
Limestone	Natural stones shaped into rubbing and polishing stones such as holystones and pumice scouring blocks
Rottenstone	Natural stones shaped into blocks for tube-mill and pebble-mill liners
Siliceous shale	Pebbles, natural and manufactured, for grinding mills
Silt	
Talc	
Tripoli	
Whiting	
<i>Manufactured Abrasives</i>	
Boron carbide	
Boron nitride	

the working face consists of diamond grit bonded with a resinoid, metal, or ceramic product; diamond-tipped tools for cutting glass and for engraving gems; diamond powder for cutting gems. High-speed tool steels, cemented carbides, and other exceedingly hard, tough alloys can be cut and shaped efficiently with diamond tools, and diamond-tipped tools are essential for the rapid and accurate shaping, truing, and dressing of abrasive wheels.

Garnet

The name "garnet" is given to a group of iron-aluminum silicate minerals having similar physical properties, crystal forms, and general chemical formula.

Composition: In garnet, general formula $3\text{RO} \cdot \text{R}_2\text{O}_3 \cdot 3\text{SiO}_2$, the bivalent element may be calcium, magnesium, ferrous iron, or manganese, the trivalent element, aluminum, ferric iron, or chromium, rarely titanium; further, silicon is also replaced by titanium in some examples. There are three prominent groups and various subdivisions under

each, many of these blending into each other. These are as follows:

- 1) Aluminum Garnet
 - A. Grossularite, calcium-aluminum garnet ($3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$).
 - B. Pyrope, magnesium-aluminum garnet ($3\text{MgO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$).
 - C. Almandite, iron-aluminum garnet ($3\text{FeO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$).
 - D. Spessartite, manganese-aluminum garnet ($3\text{MnO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$).
- 2) Iron Garnet
 - E. Andradite, calcium-iron garnet ($3\text{CaO} \cdot \text{Fe}_2\text{O}_3 \cdot 3\text{SiO}_2$).
- 3) Chromium Garnet
 - F. Uvarovite, calcium chromium garnet ($3\text{CaO} \cdot \text{Cr}_2\text{O}_3 \cdot 3\text{SiO}_2$).

Properties

COLOR—Colors vary greatly but generally are as follows:

Grossularite—white, pale green, or yellow.

Pyrope—deep red to black.

Almandite—deep red, brownish red to black.

Spessartite—brown to red.

Andradite—black, green, and yellow green.

Uvarovite—emerald green.

Hardness ranges from 6 (grossularite) to 7.5 (almandite); some almandite has a hardness of between 8.0 and 9.0.

CRYSTAL SYSTEM—Cubic, commonly as rhombic dodecahedrons or tetragonal trisoctahedrons, or in combination of the two.

CLEAVAGE—Occasionally an indistinct dodecahedral cleavage is observed; some species of almandite possess a pronounced laminated structure, these are planes of weakness along which the mineral separates, this *parting* has no relation to the crystal form and is not a true cleavage.

FRACTURE—Garnets having a glassy structure usually have a marked conchoidal fracture but sometimes the mineral tends to break into thin flakes. In other varieties the fracture is sharp and uneven.

INDEX OF REFRACTION—The index of refraction of the garnet group ranges from 1.735 to 1.94.

TENACITY—Aggregates of crystal composed of many small individuals are brittle and shatter readily. Massive garnet and well formed crystals are remarkably tough and shatter with difficulty.

FUSIBILITY—Garnets having a high iron content, such as almandite, fuse at a temperature of about 1200°C. White garnets containing a considerable percentage of chromium are infusible.

OTHER PROPERTIES—Specific gravity of the garnet group ranges from 3.5 to 4.2; luster vitreous, resinous, or dull; transparent to opaque.

Occurrence: Garnet commonly occurs as accessory minerals in a large variety of rocks, more particularly in gneisses and schists but also in contact metamorphic deposits, in crystalline limestones, pegmatites, and in serpentines. It occurs as gangue in ore veins formed at high temperatures. As most varieties of garnet are resistant to chemical and mechanical erosion, they tend to be concentrated in the sands of present-day or preexisting beaches, streams, or other alluvial deposits.

Deposits of garnet are found in many foreign countries and in nearly every state. An estimated 95% of the world's production of technical abrasive garnet comes from a small area in the Adirondack Mountains, New York State. Eighty percent of current usage of garnet is accounted for by United States industry.

The superior abrasive quality of Adirondack garnet currently being mined for technical applications is due to a combination of crystal properties including hardness (which is at the top of the garnet hardness range). This garnet, basically a combination of almandite and pyrope, exhibits incipient lamellar parting planes which break under pressure into sharp chisel-edged plates. When crushed to a very fine size it retains its natural sharp irregular grain shape. These features, particularly important in coated abrasives, are also desirable for other abrasive applications. Since Adirondack garnet occurs in large crystals a complete range of sizes results from the crushing and grinding operations necessary for liberating and separating the garnet from matrix minerals.

United States—In recent years garnet production in the United States has been confined almost exclusively to two states, New York and Idaho.

NEW YORK. Although there were at one time several technical abrasive-grade garnet producers in New York, present production is confined to one company, the Barton Mines Corp., Gore Mountain, near North Creek. This company supplies garnet to coated abrasive, glass, and metal lapping industries throughout much of the world. It has been in continuous operation since 1878 and, through technical advances enabling it to utilize leaner ores, has constantly proved new ore reserves. This mine is believed to be the country's second oldest continuous operating mine under one management and, geologically, is one of the world's most interesting ore deposits.

The almandite-bearing rock, which is an igneous-metamorphic rock of uncertain origin, lies at the surface and is quarried. The ore body is over 2 km (1¼ miles) long and ranges in width from 15.2 to 91.4 m (50 to 300 ft). The principal gangue minerals are hornblende and plagioclase feldspar which constitute from 40 to 80% of the rock. Less abundant minerals include hypersthene, magnetite, biotite, apatite, and pyrite. The garnet content of the ore body ranges from 20 to less than 5% and averages slightly less than 10%. The garnet occurs as crystals, mostly imperfectly developed, known locally as "pockets." These range in size from a fraction of an inch to more than a foot in diameter. Occasionally crystals up to 914 mm (36 in.) in diameter have been seen; however, their average size is less than 102 mm (4 in.).

Nearly every crystal of garnet is surrounded by a rim of coarsely crystalline hornblende. The quarry faces present a striking appearance, showing crimson-red garnet crystals set in a coal black background. Specific gravity of the garnet averages about 3.95, while the hornblende ordinarily is 3.07 to 3.24, with some specimens of very dense hornblende having been found with a specific gravity as high as 3.40. The general matrix is diorite.

Elsewhere in New York, garnet is produced as a by-product of wollastonite mining at Willisboro by Interpace Corp. and is sold in graded form from sandblasting operations in the Northeast. This garnet occurs as loosely cemented fine crystals that appear to be remnants of weathering and water deposition within preexisting stream channels or along shorelines.

IDAHO. The only other important producer of abrasive garnet is the Sunshine Mining Co.'s subsidiary, Idaho Garnet Abrasive Co., whose deposit is on Emerald Creek and whose plant is at the creek's mouth near Fernwood, Benewah County, Idaho. This company works an alluvial deposit of almandite garnet, derived from the erosion of soft mica schists in which the garnets have a maximum grain size of about 4.8 mm (¾ in.).

The garnet-bearing gravel is mined by dragline.

Foreign Countries—Garnet is or has been commercially mined in Madagascar, Japan, Argentina, India, and Tanzania. Garnet mining in Russia has been reported but details regarding mining are not known.

Silica

Silica Sand: Silica sand is extensively used for pressure blasting, for the initial grinding or surfacing of plate glass, and as a cutting medium for gang saws on stone.

For pressure blasting, the main centers of production in the United States are Ottawa, IL, and Cape May, NJ. The Ottawa material occurs as a friable sandstone, which is broken down to its natural grain, washed, and screened. The grains are spherical in shape. The Cape May sand is sub-

angular and uneven in shape but larger grain sizes are obtainable, more so than with the Ottawa sand.

In Canada, pressure blast sand is obtained from the decomposed rock containing friable quartz and china clay at Lac Remi, north of Montreal, Que.; from a similar type of material near Smoky Falls, north of Lake Nipissing, 40 km (25 miles) west of North Bay, Ont.; also from a friable quartzite at East Templeton, Que., a few miles northeast of Ottawa, Ont. The grain of the Canadian sands is sharp. The ranges of grain size are approximately: No. 1 between 20 and 35-mesh for light work; No. 2 between 10 and 28-mesh; No. 3 between 6 and 10, and No. 4 between 4 and 8-mesh. The last two are used for the heavy cast-iron work and steel work.

Pure, clean beach and river sands and Illinois sand are used for the preliminary or coarse surfacing of plate glass. The crushed sand is water-graded into a number of grades at the glass plants and fed to the surfacing machines. Approximately three tons of sand are required to surface one ton of plate glass.

Cutting sand, composed of sharp, solid quartz grains, is used as an abrasive for sawing stone. It is usually ungraded and about equivalent to a No. 1 pressure blasting sand.

Burnishing sand is a fine, rounded-grain silica sand of uniform size between 65 and 100-mesh, used in rolling down and burning gold decorations on porcelain.

Quartz: Crushed and graded quartz is used for the abrasive backing of "flint" sandpapers. Almost any deposit of massive white quartz is suitable. Being the cheapest of all the abrasive-coated paper, it still is sold in fair amount, mainly in hardware stores and by small jobbers. It is made only in the form of paper, not as cloth. True chalk flint from England and France is extensively employed for this purpose in Europe and has better cutting qualities and longer life than ordinary quartz.

Powdered quartz and silt are sometimes used for scouring compounds and for the harsher metal polishes.

Soft Siliceous Powder Abrasives: Many natural highly siliceous materials either occur as a powder or are used only in the powder form for mild abrasives. For the majority of these, use as an abrasive is of minor importance as compared with their principal applications.

Diatomite—Diatomite production in the United States comes primarily from California and Nevada with small outputs from Oregon and Arizona.

The amount used for abrasives is insignificant in comparison with its other applications—most important of which are filtration, fillers and insulation. Its abrasive uses include metal (silver) polishes, dental powders and pastes, and occasionally it is used as a friction agent in the manufacture of matches.

Pumice—Under the name of pumice are included lump pumice and pumicite or volcanic dust, the natural powder. Lump pumice is used by manufacturers of furniture and musical instruments; for dressing the wood and metal surfaces; by silver platers for preparing their metal surfaces; by lithographers for cleaning stone surfaces; for rubbing down and polishing fine tools and instruments; by restaurants for scouring grills and cooking utensils, and for domestic and toilet uses, such as hand cleaners. Pumicite or ground pumice is mainly used as a cleanser, the thin, sharp, and striated grains being particularly suitable.

Tripoli, Microcrystalline Silica, and Rottenstone—The fine-grained, porous materials, tripoli, microcrystalline silica, and rottenstone, are known to the trade as "sift silicas."

Tripoli, which in the United States comes from southwest

Missouri and northeast Oklahoma, is mainly used in the form of made-up tripoli grease bricks or tripoli compositions for buffing and polishing. The compound is applied to a rapidly revolving belt or canvas wheel and used for the finishing or buffing of metals, plated products, and so forth. It is used also to a small extent in the manufacture of some scouring and cleaning powders and soaps; for the rubbing down of painted surfaces, such as automobile bodies. A similar but finer-grained material occurring in the northwest corner of Arkansas, about 80 km (50 miles) southeast of the Missouri deposits, is used mainly for oil-well drilling mud.

Microcrystalline (sometimes erroneously termed "amorphous") silica, which comes mainly from southwestern Illinois but to some extent from Wayne County, TN, also is used for buffing and polishing compounds. These compounds are termed "silica" by the trade and are much in demand for white "coloring" operations on high-class work. Chemically precipitated amorphous silicas also are used in polishing and buffing compositions.

Both tripoli and microcrystalline silica have been mined from deposits at Harrisburg, northwestern Georgia.

Rottenstone, a fine-grained gray-buff siliceous-argillaceous limestone, comes from Antes Forte, Lycoming County, PA, and is used as a polish base, for instance, for automobile polishes.

Nonsiliceous Soft Abrasives

Ground Feldspar is extensively used in scouring and cleaning compounds and for a window cleaner.

Chalk (calcium carbonate) is a soft, compact, fine-grained, white limestone composed of the calcareous remains of small marine shells. A small amount of this chalk—mainly from England and France—known as "whiting" is used as a very mild abrasive for hand polishing of nickel, gold, silver or plated ware, buttons, and similar materials.

China Clay (kaolin) and some pipe clays have been used successfully in polishing powders. Pipe clay at one time was the standard polish for naval and military tunic buttons.

BATH BRICK, used for scouring steel utensils, is made from a very fine-grained, quartzose clay found along the banks of the Parrot River in England.

STAUROLITE, a complex iron aluminum silicate, has been commercially recovered from various river placer deposits in the southeastern US. DuPont operates a deposit in Clay County, FL. It is used mostly for pressure blasting.

Sharpening Stones

Hand-used sharpening stones include scythestones, whetstones, oil stones, water stones, razor hones, holystones, and rubbing stones. While, in general, stones made from bonded artificial abrasive grains have largely replaced these natural abrasives there is still some small production of oilstones and whetstones in Arkansas, whetstones in Indiana, and scythestones in New Hampshire. Arkansas novaculite stones are still preferred for sharpening fine-edged tools for surgeons, carvers, and engravers. It is claimed that these stones give a smoother and longer-lasting edge.

Natural abrasive stones are made from a wide variety of material, including sandstone, novaculite, mica schist, siliceous argillite, shale, slate, and pumice. The superior cutting quality of some of these stones is due to the inclusion of well disseminated fine-grained inclusions of garnet or other minerals of superior hardness.

Grinding Pebbles and Tube-Mill Linings

Tube-mills, conical-mills, and cylindrical batch mills are used more often than any others for the fine grinding of hard

ores, minerals, paints, chemicals, ceramic bodies and glazes and enamels, portland cement clinker, and similar materials.

Most efficient grinding can be done in mills with iron or steel liners and iron or steel balls, slugs, or rods, but where contamination of the color or chemical purity of the product by metals and metal oxides must be avoided, the grinding surfaces consist of blocks or bricks for the mill linings and natural pebbles or artificially prepared balls.

The most favored natural mill-lining material for most purposes is Belgian silex, which is a very hard, tough, more or less cellular quartzite resembling French buhrstone. This is imported in rectangular blocks more or less shaped to fit the curve of a mill. During World Wars I and II, when imports were cut off, and to a much lesser extent at other times, domestic substitutes have been used. These have consisted chiefly of quartzite from near Jasper, MN; Iron City, TN; and Baraboo, WI; and granites from Salisbury, Lilesville, and Faith, NC. Some of these materials are reported to give service equal to that of Belgian silex. Special hard, dense, porcelain blocks are used in some mills for grinding paint, ceramic, and chemical materials.

For grinding media, Danish flint pebbles, when available, have long been standard because of their superior hardness, toughness, and uniformity. These pebbles are found on the shores of Greenland but are marketed through Denmark. Other foreign sources of similar pebbles exist along the sea-coasts of Belgium, France (between Le Havre and St. Valery-sur-Somme), Norway, and England. Seven sizes of Danish pebbles are marketed, ranging from 25.4 to 203 mm (1 to nearly 8 in.).

Domestic substitutes for grinding media are natural pebbles of flint, quartz, and quartzite, as well as artificially rounded (by tumbling small blocks in rotating cylinders) pebbles made from quartzite, granite, chalcedonized rhyolite, and other rocks. During World War II, pebbles were shipped

from Encinitas Beach, CA (true flint); from Jasper, MN (quartzite); from the Austin chalk beds in south-central Texas (true flint); from Salisbury and Faith, NC (granite); from Baraboo, WI (quartzite), and several other points in the United States. Extensive deposits of quartzite pebbles in southwestern Saskatchewan have been reported. Beach pebbles were reported nonuniform in hardness and requiring careful sorting.

17. Nepheline Syenite*

Nepheline syenite is a silica deficient crystalline rock consisting of albite and microcline feldspars and nepheline, together with varying but small amounts of mafic silicates and other accessory minerals. Nepheline-bearing rocks are widely distributed around the world but only in Canada, Norway, the Union of Soviet Socialist Republics, and the United States are deposits worked commercially.

Because of its low melting point and fluxing ability, nepheline syenite was investigated in the early 1900s by many students of glass and ceramics. Although the nepheline syenite deposits in Methuen Township, Ont., Canada, were discovered as early as 1897, it wasn't until 1935 that the first mill was erected to produce nepheline syenite products.

In Canada, nepheline syenite deposits are worked by Indusmin Ltd. and International Minerals and Chemical Corp. (Canada) Ltd. who have combined production capacity in excess of 1800 stpd. In Norway, the Norsk Nefelin Div. of Elkem Spigerverket has produced nepheline syenite from a deposit on Stjernöy Island in western Finland since early 1960.

Nepheline syenite has been under investigation in the Union of Soviet Socialist Republics (USSR) since at least 1928. In 1951, the first commercial alumina works was brought on stream at Volkhov, near Leningrad, utilizing nepheline concentrates from the Kola peninsula as mill feed. Since then two others have been completed and more are planned. Large quantities of portland cement, sodium carbonate, and potassium carbonate are produced in conjunction with the alumina.

A material called nepheline syenite, but actually a pulaskite, is produced in Pulaski County, Arkansas, by the McGeorge Construction Co. for construction aggregates and by the 3M Co. for roofing granules. The Dome Fill Co. purchases the fines and uses them in the preparation of enclosed construction fill.

Chap. 16 on "Feldspar, Nepheline Syenite, and Aplite" in the 3rd ed. of *Industrial Minerals and Rocks* (Castle and Gillson, 1960) and *Nepheline Syenite Deposits of Southern Ontario* (Hewitt, 1960) contain excellent accounts of earlier commercial development of nepheline syenite as a glass and ceramic material. An English monograph on *Nepheline-Syenite and Phonolite* (Allen, et al., 1968) is a complete survey, at the time, of nepheline syenite which, with its very complete list of references, is an excellent source book.

END USES

Nepheline syenite from the Canadian and Norwegian producers finds use primarily in the manufacture of glass and ceramics. One producer also makes several grades of nepheline syenite that are useful as extender pigments and fillers in paint, plastics, and rubber. In the Soviet Union nepheline is used in increasing quantities in the manufacture of alumina, alkali carbonates, and portland cement and to a lesser degree in the manufacture of colored container glass.

Glass

By far the largest use of nepheline syenite is in the manufacture of glass products including container glass, fiber

glass, opal glass, plate glass, sheet glass, and tableware glass. Nepheline syenite provides necessary additions of alumina and alkalis in the glass batch; it is low in silica and contains no free quartz; it has a favorable ratio of sodium oxide to potassium oxide of 2/1. Nepheline syenite bearing glass batches have lower viscosity and easier workability compared with those containing potash feldspar.

The lower fusion point of nepheline syenite lowers the melting temperature of the glass batch with attendant faster melting, high productivity, and fuel savings.

Ceramic Ware

Nepheline syenite is being used for the manufacture of a wide variety of whiteware products including dinnerware, sanitaryware, floor and wall tile, electrical porcelain, art pottery, chemical porcelain, dental porcelain, porcelain balls, and mill liners. In ceramics, nepheline syenite serves as a vitrifying agent, contributing to the glassy phase which binds other constituents together and gives strength to the ware. The ready fusibility and abundant fluxing capacity of nepheline syenite benefits manufacturers by permitting reduced body flux content, lower firing temperatures, or faster firing schedules than could be attained with other raw material combinations.

Extender Pigment and Fillers

Applications for nepheline syenite as extender pigments and inert fillers have been found and developed. These include exterior and interior latex and alkyd paint systems, traffic paints, metal primers, exterior wood stains, sealers, undercoats, and hardboard ground coats. Nepheline syenite for these products has desirable high dry brightness, high bulking value, low vehicle demand, extreme ease of wetting and dispersion, and a stabilizing pH value. In paint formulations, nepheline syenite has exceptionally good tint retention characteristics.

In plastics, nepheline syenite has found increasing use in rigid, flexible, and plastisol-type polyvinyl chloride, and in epoxy and polyester resin systems. It exhibits extremely low resin demand thus making high loadings possible. In PVC resins, it exhibits extremely low tinting strength, has a refractive index close to that of vinyl resin, and has a very low optical dispersion. It has a specific gravity lower than calcium carbonate and talc and the properties described for paint applications are beneficial in plastics applications as well.

Nepheline syenite is also used as an inert filler in the manufacture of foam carpet backing.

Alumina

In the USSR, nepheline syenite and nepheline are used to manufacture alumina for aluminum production, sodium and potassium carbonates, and portland cement. USSR production comes from Kola peninsula and Kiya Shaltyrsk deposits. The US Bureau of Mines (Anon., 1961-71) estimates that the present level of consumption of nepheline concentrates in the Soviet Union is 1 Mt (1 million tpy). More recent data on nepheline syenite production in the USSR are not available. In addition, the Volkhov, Pikalevo, and Achinsk alumina plants require at least 3 Mt (3 million lt) of nepheline syenite annually. Nowhere at this time outside the Soviet Union is nepheline or nepheline syenite used as the basis for such industries.

*Excerpt from Minnes, D.G. (revised by Lefond, S.J., and Blair, R.E.), 1983, "Nepheline Syenite," *Industrial Minerals and Rocks*, 5th ed., Vol. 2, S.J. Lefond, ed., AIME, New York, pp. 931-960.

Product Specifications

Nepheline syenite used by the glass industry is characteristically a -30 mesh +200 mesh product having an alumina content in excess of 23%, alkali content in excess of 14%, and iron oxide content less than 0.1%. Other metallic contaminants must be very low. For the ceramic industry nepheline syenite is ground to typically -200 mesh and is characterized by its high fluxing and low level of iron and other impurities. For extender pigment and filler industries, nepheline syenite offers high dry brightness, uniformity, chemical inertness, and specific index of refraction and is supplied in various finenesses.

Market requirements vary and while the European markets accept a 0.1% Fe_2O_3 content, North American markets require 0.08% Fe_2O_3 or less. Norwegian nepheline syenite products are higher in alumina and alkalis than Canadian ones. Other contaminating metallic ions must be at acceptably low levels and refractory minerals must be absent.

GEOLOGY

Mineralogy

Nepheline syenite is a coarse to medium-grained crystalline rock generally considered of igneous origin in which the essential mineral constituents are microcline, orthoclase or albite feldspars, the feldspathoid nepheline, and ferromagnesian minerals of which the principal are hornblende, pyroxene, and biotite. The most frequently occurring accessory minerals include magnetite, ilmenite, calcite, garnet, zircon, and corundum. Nepheline syenites are quartz-free. Commercial deposits of nepheline syenite contain at least 20% nepheline, at least 60% feldspar, and seldom more than 5% accessory minerals. For a deposit to be of interest, refractory minerals such as corundum and zircon must be absent or easily removed along with other accessory minerals and characterizing mafic silicates during processing.

Nepheline: Nepheline is the most common of the feldspathoid minerals. Its formula is $\text{Na}_3\text{KAl}_4\text{Si}_4\text{O}_{16}$. Potassium is always present in natural nepheline, most frequently in ratio amounts of Na/K: 3/1, although ratios of 4/1 and 6/1 are known. It crystallizes in the hexagonal system and frequently forms 6- or 12-sided prisms. It has a distinct and an imperfect cleavage and a subconchoidal fracture. It is brittle; the hardness is $5\frac{1}{2}$ to 6 on Mohs' scale, the specific gravity is 2.5 to 2.7; the luster is vitreous to greasy, occasionally opalescent. It is colorless, white, or yellowish but when massive may be dark green, greenish, bluish-gray, brownish-red, and brick red. It is also known as claeolite. It gelatinizes readily in acid and because it is more soluble than associated minerals can be readily spotted in outcrops by the pitted appearance of the rock surfaces. Nepheline alters to various zeolites, analcite, sodalite or cancrinite, and the giesckite micaceous materials.

Feldspar: The major feldspars present are microcline and orthoclase with a theoretical composition SiO_2 64.7%, Al_2O_3 18.4%, and K_2O 16.9%; and albite with a theoretical composition SiO_2 68.7%, Al_2O_3 19.5%, and Na_2O 11.8%.

Pyroxene: The aegerine member of this series of minerals is customarily present in feldspathoid rocks but the theoretical composition ranges from aegerine SiO_2 52.0%, Fe_2O_3 34.6%, and Na_2O 13.4%; to that of diopside SiO_2 55.6%, CaO 25.9%, and MgO 18.5%.

Amphibole: A wide variety of amphiboles are present in nepheline syenites including hornblende, hastingsite, barkevikite, arfvedsonite, and riebeckite. These are calcium, mag-

nesium, sodium, and iron aluminosilicates of various compositions.

Biotite: Two types of biotite are found in feldspathoid rocks; the golden-brown variety, but more frequently the high-iron variety lepidomelane. It is a hydrated aluminosilicate of potassium, iron, and magnesium.

Accessory Minerals: Among the more frequently found accessory minerals are sodalite, noselite, hauynite, scapolite, cancrinite, calcite, apatite, magnetite, ilmenite, hematite, pyrite, zircon, sphene, pyrochlore, garnet, and corundum.

Nepheline syenites have a wide variety of textures which can be generally classified according to the origin of the rock; plutonic and hypabyssal nepheline syenites; nepheline syenite pegmatites, and the migmatic nepheline rocks or "nephelinized gneisses."

Classification of Deposits

Several methods can be used to classify nepheline syenite deposits—by the percentage of principal minerals present in the deposit, by their origin, and also by their color. Nepheline syenites have been studied intensively and works by Deer, et al. (1963) and Eitel (1965) provide an introduction to complete studies of nepheline and nepheline syenite. Little information about worldwide nepheline syenite occurrences and their commercial potential was available in concise form until publication of *Nepheline-Syenite and Phonolite* by Allen and Charsley in 1968. The book is an excellent summary of the present state of commercial interest in this and allied rocks.

Although a wide variety of names have been given to nepheline-bearing rocks and the term nepheline syenite is often given to any such rock containing 5% or more nepheline, it is unlikely that a rock would be of commercial interest unless the nepheline content is at least 20%.

Nepheline Syenite Deposits: Deposits are rarely of great areal extent, the largest being those in the Kola peninsula of the Soviet Union [1165 and 647 km^2 (450 and 250 sq miles)], Brazil [777 and 259 km^2 (300 and 100 sq miles)], and Greenland [207 km^2 (80 sq miles)]. Most others are typically much smaller, less than 52 km^2 (20 sq miles), and those in Blue Mountain, Ont. 7.8 km^2 (3 sq miles), and Stjernöy, Norway [0.5 km^2 (0.2 sq miles)] are even smaller. Classification may also be made based on the mode of occurrence and origin of the nepheline syenite. Moorhouse (1959) for one has divided them into five groups:

- 1) Feldspathoid rocks associated with undersaturated volcanics.
- 2) Differentiated ring complexes, often associated with carbonatite and usually characterized by metasomatism around their borders.
- 3) Layered intrusives, possibly related to the ring complexes.
- 4) Borders or satellitic stocks associated with syenites or granites.
- 5) Nephelinized gneisses, usually associated with nepheline pegmatites.

The first type has no economic significance. Examples of the others would be: group 2, Nemegos, Ont.; Mont St. Hilaire, Que.; and Kola peninsula, Karelian ASSR; group 3, Ice River, B. C.; Julienhaab, Greenland; group 4, Blue Mountain, Ont.; group 5, Stjernöy, Norway.

A variety of origins are possible (Turner and Verhoogen, 1951): from low temperature residual magmas which have been conditioned by volatile components; by fractional crys-

tallization of undersaturated olivine-basalt magma; by desilication of granitic magmas, that might have invaded the limestone with evolution of a CO₂-rich gas phase which may be important; nepheline syenite magmas, and metasomatic alteration of various preexisting rocks, i.e., "nephelinization."

Distribution of Deposits

Nepheline-bearing rocks are widespread throughout the world and deposits of nepheline syenite are common. Those in Canada, the United States, Norway, and the Union of Soviet Socialist Republics have been well described and much is known about those in other countries of Asia, Africa, and the South Pacific. Two of the largest known are the Khibiny [1165 km² (450 sq miles)] and Lovozero [647 km² (250 sq miles)] intrusives in the Karelian ASSR (Vlasov et al., 1966) of the USSR. Other large ones are located in Siberia. In Brazil, nepheline syenites occur in several extensive intrusive areas, the largest of which cover some 777 km² (300 sq miles) in Minas Gerais and São Paulo, and 259 km² (100 sq miles) in São Paulo. Other deposits are rarely large, seldom covering more than a few square miles or a few tens of square miles in area.

However size is not an overly important criterion in commercial considerations; more important are the purity and location of the deposits.

There are now seven known mining ventures in different parts of the world producing nepheline or nepheline syenite products; two in Canada, one in Norway, two in the USSR, and two in the United States.

In Canada, nepheline syenite deposits are common in several provinces. Occurrences in the vicinity of Lake Alabanel, Gouin, Labelle, Mont St. Hilaire, and Oka, Que., are well known. In Ontario, Hewitt (1960) has described deposits in the vicinity of Blue Mountain, Haliburton-Bancroft, French River, Callander Bay, Nemegos, and Port Caldwell as well as other minor occurrences. In British Columbia, the Ice River and Kruger Mountain complexes are well known. Much of the interest in Canadian deposits has stemmed from the successful development of the Blue Mountain intrusive in Methuen Township but none other has proven pure enough to warrant exploitation.

In Norway, nepheline syenite is known in the vicinity of Oslo and on several islands in western Finland, although only that on the southwest side of Stjernöy Island has the necessary characteristics for commercial development.

Reserves: The only known deposits of nepheline syenite suitable for low-iron products are being mined at existing operations in Norway and Canada. Reserves are considered limitless. In Norway at Norsk Nefelin, the volume of proven nepheline syenite exceeds 135 million m³ representing nearly 400 million tons of rock of a nature the company considers suitable for mining. In Canada, Indusmin has published a reserve figure of 14 million tons of proven ore, sufficient for 35 years at present mining rates. The company owns 85% of the Blue Mountain intrusive and believes potential reserves of minable rock are satisfactory for an indefinite period.

International Minerals and Chemical Corp. (Canada) Ltd. owns 202 ha (500 acres) of nepheline syenite at Blue Mountain, Ont. Reserves are considered to exceed 30 million tons, ample for any production requirements.

In the Soviet Union, there are no firm indications of reserves of nepheline-bearing rocks suitable for chemical conversion. The estimated production of apatite from the Kola peninsula mines exceeds 27 Mt/a and consequently the operation generates more than 35 Mt of nepheline-bearing tail-

ings annually from which an estimated 15 Mt of nepheline concentrate could be recovered. In addition many square kilometers of nepheline syenite are present so reserves can be considered adequate for projected chemical needs. Nepheline syenite reserves at Goryachegorsk in central Siberia have been estimated at over 100 Gt.

EXPLORATION

As with most industrial minerals the "place value" of a nepheline syenite deposit is critical. In addition to the following comments on field examination, the exploration geologist should consider the overriding importance of costs of production and the costs of transporting products to market.

Only by examining the interrelationship of all factors bearing on exploitation of a given nepheline deposit can one determine if development is warranted.

Field Techniques

The field geologist needs to search for a deposit that consists of a coarse to medium-grained rock. Crushing to minus US Standard 30 mesh should liberate all the impurities that need to be removed before a product is salable. Careful mapping of the deposit in detail will reveal textural, structural, and mineralogical changes that might affect mining. Samples need to be selected carefully to provide a representative suite on which initial microscopic, physical, chemical, and ceramic tests can be made.

If examination reveals that impurities are scattered through the feldspar crystals in a finely divided state, such a deposit would be unsuited for glass and ceramic uses. Only if impurities can be readily liberated by crushing should a deposit receive more detailed evaluation. One would normally expect to mine feldspathic materials by open pit methods and due consideration needs to be given to bench heights, berms, and mining regulations when determining if a given deposit would be satisfactory. Ore reserves should be large enough to sustain an operation for a long time because customers demand assurance of ample supply and, in industrial mineral ventures, ten or more years may be needed to repay the invested capital. Normally one would not consider a deposit having ore reserves for less than 20 years operation.

Consideration must be given to possible methods that might be used to beneficiate nepheline syenite from a deposit. Present feldspar and nepheline syenite beneficiation plants have relatively simple schemes for flotation and electromagnetic removal of impurities, and flotation separation of quartz and feldspar. Flotation, electrostatic, electromagnetic, and other techniques can all be successfully used on different mineral assemblages but if the mineral suite in a given deposit is too complex, the combination of techniques needed to remove impurities could well be too expensive and involve too many operating variables to permit economical operation.

In areas where chemical weathering is a factor, one must have fresh specimens with which to work. Nepheline dissolves from rock surfaces relatively easily, feldspars are altered to kaolin, iron oxides and sulfides may be leached away, all of which tends to distort results obtained when surface samples are examined.

Complex nepheline syenite deposits such as the ring-complex type and carbonatite type intrusives show little promise for utilization in glass and ceramics. They are too variable in normal feldspar and mafic constituents and furthermore may contain rare earths, halides, and numerous

other trace elements that detract from the intended applications for the rock.

Nepheline syenite deposits of the sheet, gneissic, and border phase of granite and syenite intrusive types seem to offer the greatest chance of uniformity and quality needed.

Drilling

Deposits of merit need to be drilled to confirm the nature of the rocks and to provide samples for laboratory work. Depending on circumstances, AX, BX, and NX diameter core may be recovered. In laying out a drill program, care must be taken that holes intersect all rock types at appropriate angles of inclination. Bands of biotite gneiss, for instance, might be erratic in distribution and unless drilling is adequate, erroneous conclusions might be drawn about the amount of such impurities present. A deposit may be zoned and, although mapping indicates rock of one type, the core of the deposit may be another. There are always variations to be encountered in nepheline syenite deposits, as may be guessed from their mode of origin, and drilling a deposit provides assurance that surprises will be minimal.

Spacing of drill holes is determined by the uniformity of the rock and the stage of the investigation. Initial drilling is widespread, followed by grid drilling at perhaps 122-m (400-ft) spacing, followed by spacing of 30.5 m (100 ft) or less if conditions demand.

Geophysical and geochemical techniques are not a normal part of exploration for nepheline syenite although seismic surveys may be useful for helping to determine the depth of overburden.

Other Considerations

Consideration should be given to matters such as the size and character of the market, the mode and cost of transportation, availability of auxiliary services, labor supply, and laws that might be restrictive. Due concern for them at an early stage in exploration could provide a basis for judging which deposits have the greatest worth and save much time and wasted expense on further laboratory evaluation permitting one to study the rock for signs of product warrants.

18. Olivine*

Olivine is a mineral containing a mixture of forsterite (Mg_2SiO_4) and fayalite (Fe_2SiO_4) in solid solution. The name *olivine* was first applied by Werner in 1790 (Hunter, 1941) because of the olive-green color of the mineral.

Olivine is the principal component of the rock dunite, which itself is a member of the peridotite group of ultrabasic igneous rocks. European uses of the terms *olivine* and *dunite* are somewhat different than US usage. In commerce European usage defines *dunite* as containing 36 to 42% MgO , 36 to 39% SiO_2 , and loss on ignition of approximately 10%. The term *olivine* is used to designate a material containing approximately 85% forsterite, with a chemical composition of approximately 45 to 50% MgO , 40 to 43% SiO_2 , 5 to 8% Fe_2O_3 , and ignition loss of 1 to 2%.

USES

The principal use of olivine is in various applications involving hot metal. In excess of 90% of world uses involve hot metal, with approximately 75% as a slag conditioner in the blast furnace production of pig iron. Approximately 15% of total olivine usage is as a special foundry sand in mold making for the brass, aluminum, magnesium, and manganese steel foundries (Schaller, 1957, 1958; Snyder, 1957; Anon., 1977).

Olivine was first used as an industrial mineral in the early 1930s for a refractory material (Anon., 1970; Hunter, 1941). As a refractory raw material, olivine was first introduced in the United States as hand-cobbed, selected, shaped blocks of crude olivine. This use met with limited success. More recently, finely ground olivine blended with MgO and pressed into bricks, which are then fired, has found use in glass tank furnaces and open-hearth furnaces. Ramming or gunning mixes for basic furnace linings also utilize olivine. Olivine has been used in ladle linings with varied success. In Europe, substantial tonnages of olivine are utilized in refractory brick for night storage heaters (Anon., 1970).

A limited amount of olivine has been used in the past as a fertilizer (magnesium source) and has been used with rock phosphate to produce a magnesium phosphate as a plant food. The relatively high magnesia (MgO) content of olivine also attracted attention to it as a potential source of both magnesium compounds and as a source of metallic magnesium (Bengston, 1956; Hunter, 1941). The use of olivine as an additive in the blast furnace is relatively new, having been developed during the last two decades.

As a foundry sand olivine is used in mold making for the brass, aluminum, magnesium, and manganese steel foundries. It has a fusion point of approximately 1816°C (3300°F) and lower thermal expansion than silica; thus, it exhibits less defects in the castings such as "rat tails," "scabs," and "buckles." Little or no free silica occurs with olivine, so the silicosis hazard is reduced as compared to the use of normal silica sand in foundry applications.

Normally, coarse sand is used in manganese steel foundries and the finer sands in aluminum, magnesium, and brass foundries. Fine sand is used in the manufacture of "hot tops" where quartz sand is not permitted because of health hazards.

Industries using olivine have not standardized specifications. Normally, producers supply a product which meets individual customer requirements. Such requirements involve type and amount of impurities, grain size of product, refractory characteristics chemical analysis, etc.

GEOLOGY

Olivine occurs commonly as accessories in basic igneous and basic metamorphic rocks. Economic deposits are of magmatic origin and are restricted to essentially the dunite variety of peridotite. Dunites are medium to coarse-grained crystalline rocks, generally reddish brown on weathered outcrop, and are composed primarily of olivine.

Mineralogy

The name *olivine* is a generic term used to indicate a group of orthosilicate minerals in isomorphous series, with magnesium-rich forsterite (Mg_2SiO_4) and iron-rich fayalite (Fe_2SiO_4) as end points (Ramberg and DeVore, 1951; Reed, 1959). In commercial practice, use of the term olivine applies to deposits containing a mixture of forsterite and fayalite in solid solution with fayalite content usually restricted to less than 15%. Accessory constituents may include the primary minerals: ilmenite, magnetite, chromite, and garnet; and various secondary minerals as alteration products.

The chemical composition of typical olivine may be expressed either as $(\text{Mg},\text{Fe})_2\text{SiO}_4$ or as $2(\text{Mg},\text{Fe})\text{O} \cdot \text{SiO}_2$. The ratio of $\text{Mg}:\text{Fe}$ varies from 16:1 to 2:1, passing from forsterite on the one hand to fayalite on the other.

Mode of Occurrence and Origin

Commercial olivine occurs as alpine-type and zoned dunite bodies. Controversy exists among various researchers concerning the origin and mode of emplacement (Astwood, et al., 1972; Bennett, 1940; Bowen and Schairer, 1935, 1936; Gaudette, 1963; Mossman, 1972; Ragan, 1959, 1961; Ross, et al., 1954; Yudin, 1959). There is general agreement, however, that most olivines have been emplaced in a partially crystallized condition (mush) and that in part, at least, foliation present in many unmetamorphosed dunites results from flowage during emplacement prior to complete crystallization.

All commercial bodies are of igneous origin and may be in part magmatic segregates from basic magmas. Domestic olivine bodies, of present or potential economic importance, range in age from pre-Ordovician for the North Carolina deposits, to post early-Tertiary age for the Washington dunites.

Distribution of Deposits

Large deposits of olivine-bearing dunites crop out in Norway, Sweden, USSR, Austria, Japan, New Zealand, Zimbabwe, South Africa, United States, New Caledonia, Italy, Greece, Spain, India, Brazil, and Canada (Anon., 1970; Bennett, 1940; Brothers, 1960; Du Rietz, 1935; Francis, 1956; Gwinn, 1943; Hunter, 1941; Ragan, 1961; Roberts, 1947; Yudin, 1959).

In the United States, numerous lenslike bodies extend in a belt from northeastern Georgia, northeastward across western North Carolina. Some 25 of these deposits are relatively fresh, with each containing up to five million tons of recoverable olivine.

*Excerpt from Teague, K.H., 1983, "Olive," *Industrial Minerals and Rocks*, 5th ed., Vol. 2, S.J. Lefond, ed., AIME, New York, pp. 989-996.

Many small to large dunite bodies occur in northwestern Washington, with the Twin Sisters deposit being the largest.

Taylor (1967) describes eight zoned ultramafic complexes in southeastern Alaska containing cores of dunite. Some of these olivine cores are as great as one mile in diameter.

Reserves

The largest body of olivine in the United States is the Twin Sisters deposit in Whatcom and Skagit Counties, Washington. This dunite has an outcrop area of approximately 93 km² (36 sq miles) and has a relief of about 1.5 km (5000 ft).

Other countries containing large reserves of olivine include Norway, where the Aaheim deposit is reported to contain two billion tons. Several other Norwegian deposits contain up to five million tons. In Sweden the largest deposit is at Arutats and is reported to be comparable in size to the Twin Sisters deposit. In Austria large deposits of serpentized-olivine occur in the Province of Styria. Scotland, Spain, and Italy contain large deposits of serpentized olivine. In New Zealand, the Dun Mountain dunite is reported to be approximately 2.4 km (1½ miles) in diameter. This deposit is located near Nelson, New Zealand (Gwinn, 1943). A dunite deposit in the coastal area of southern New Zealand has been described by Mossman (1972) "as exceeding 600 meters in thickness." This occurrence apparently is a magmatic differentiate in the Greenhills Ultramafic Complex.

Unaltered dunite crops out as a lenslike body approximately 40 km (25 miles) south of Ste. Anne des Monts on the Gaspé Peninsula of Quebec, Canada. Dunite is also reported in Newfoundland.

EXPLORATION

Most of the dunites containing economic olivine outcrop as prominent ridges or domes. Soils developed from the weathering of dunites support limited vegetation, thus many deposits crop out as "balds."

As a first step in exploration, an olivine deposit should be thoroughly investigated by reconnaissance techniques followed by detailed topographic and geologic mapping. Grab samples, representing various varieties of dunite which occur in the deposit, should be collected for petrographic and chemical evaluation. Grain size, alteration products, and distribution of impurities should be noted, both in samples and throughout the deposit. Portions of the deposit covered with soil should be trenched to determine whether or not the bedrock is olivine. For example, some of the North Carolina olivines, originally regarded as being relatively continuous, have shown by trenching and drilling that areas covered by soil are underlain by non-olivine material that has resulted from alteration of the olivine.

After the surface extent of the olivine deposit is established, details of vertical variation should be determined. As most olivine bodies in the Southeastern deposits are rather closely fractured and jointed and may contain alteration products considerably softer than olivine, core drilling is not recommended for determining vertical continuity. Some variety of percussion drilling, such as Air-Trac drilling or down-the-hole drilling is normally superior to core drilling in olivine deposits. The driller can note variations in drilling rates as well as character of cuttings. If the drill is equipped with a vacuum pump, continuous samples of cuttings can be collected and evaluated.

EVALUATION OF DEPOSIT

A commercial olivine should contain in excess of 40% MgO, before any beneficiation. Many olivine deposits, such

as Twin Sisters in Washington, and those in Norway and Sweden, are relatively pure and are amenable to evaluation by dry crushing, followed by screen analysis of the crushed product and chemical and petrographic analysis of the various size fractions. Refractory characteristics also should be determined on the various screen sizes.

Olivine samples which contain objectionable impurities can be evaluated by crushing to a size that will permit removing these impurities and evaluating the clean olivine. Perhaps the most efficient laboratory method to accomplish removal of impurities from crushed or broken samples is to use heavy liquids. Most objectionable impurities which occur with olivine "float" on a liquid of specific gravity of about 3.0. Accessory chromite and olivine report as "sinks." If complete liberation is obtained prior to separation with heavy liquid, the resultant olivine product can be evaluated as outlined previously. Olivine deposits, which require beneficiation in order to produce a usable olivine concentrate, should yield at least 65% product to be considered commercial.

Most accessory minerals associated with olivine lower its refractory characteristics. For example, serpentine, chlorite, and vermiculite contain 12 to 17% water of crystallization, and unless these materials are removed from the olivine, they will contribute to a high loss-on-ignition of the product. Also, the platy minerals, chlorite and vermiculite, react explosively when heat shocked. Olivine sands which are to be coated should contain a minimum amount of platy minerals because of the surface area-weight ratio.

19. Perlite

FREDERIC L. KADEY, JR.

Perlite, as a volcanic glass, has been recognized since the 3rd century, BC (Langford, 1978).

Today the name perlite is applied to both the hydrated volcanic glass, generally of rhyolitic composition, and to the lightweight aggregate that is produced from the expansion of the glass after it has been crushed and sized.

For the purpose of this discussion, however, only the unexpanded ore will be considered. Petrologically, it was originally described as a glassy rhyolite that had a pearly luster and concentric, onionskin parting (Johannsen, 1939). Since the end of World War II when its commercial significance as a lightweight aggregate became important, other textures associated with the classical texture have become included within the definition of perlite and will be described herein.

GEOLOGY

Occurrences of perlite are restricted to several Tertiary to Quaternary age rhyolitic belts that trend in a generally north-south direction around the world. Commercially suitable deposits generally occur as domes of several hundred feet in height, although glassy zones in welded ash-flow tuffs and others associated with dikes and sills also have been reported. Mining is by ripping and blasting from open pits. Nowhere in the world has it been found economical to extract perlite as an underground operation.

In the United States, New Mexico leads in production with Arizona, California, Nevada, Idaho, and Colorado following in approximately that order. The principal use for expanded perlite is as a lightweight insulating aggregate in cryogenics, in plaster, concrete, and in loose fill insulation. Expanded perlite is also used in horticultural applications, and, after subsequent milling and classification, as a filter aid.

The United States is the world's largest producer and consumer of perlite. In its naturally occurring form, perlite is a rhyolitic glass that contains from 2 to 5% combined water. While perlite also can occur as andesitic or dacitic glass, these latter types are of negligible commercial significance. Table 1 lists the chemical composition of a few typical perlites (Anderson, et al., 1956; Langford, 1979).

What sets perlite of commercial significance apart from other volcanic glasses is the fact that under the proper conditions of preparation—crushing and sizing—it will, when rapidly introduced into a flame of sufficient temperature, expand or “pop.” All of the elements of composition contribute to the expansibility of the rock. The role of the combined water, however, is the most significant because it is believed not only to produce a fluxing effect in the softening of the highly siliceous glass prior to expansion, but it is also responsible for the explosive force of expansion through volatilization during heating. The current theory of the origin of water in perlite is now less controversial than it was a decade earlier. The 2 to 5% range for total combined water in perlite was originally thought to have been chilled or frozen into the glass as it was injected under an ice sheet or into a lake (Hunting, 1949). Now, there is universal acceptance of the theory that perlite was formed by the secondary hydration of obsidian after its emplacement (Ross and Smith, 1955; Friedman, et al., 1966; Jesek and Noble, 1978).

Studies have shown that the combined water in perlite exists in at least two forms (Lehmann and Knauf, 1973; Lehmann and Rossler, 1974): one as molecular water and the rest as hydroxyl water. The ratio of one kind of water to the other is different for perlites of different origins. The composition of the perlite, particularly the amount of MgO and CaO, is believed to influence the rate of hydration of the obsidian.

An emplacement model for perlitic domes suggests that the outermost material will be pumiceous, grading inward into increasingly more compact textures and finally into a felsitic core. The following textures that fit the model have been observed at No Aqua Mountain, New Mexico, and elsewhere (Whitson, 1982). While these textures also may be known by other names, the following seems to be a convenient and logical nomenclature.

Pumiceous

Near surface, this is a lightweight and frothy perlite where vesiculation is less confined by lithostatic and hydrostatic pressures. The vesicularity and the degree of distortion of the vesicles is a function of local confining pressures and of the amount of the supercooled liquid. Flattening of vesicle walls increases with depth while elongation occurs during flow. Hence, in depth, the vesicles of pumiceous perlite when viewed with an X10 hand lens appear elongated and taffylike.

At the No Aqua deposit, this taffylike texture—shardy—while actually a gradational subunit of the pumiceous textured material has different and commercially advantageous properties compared with the more vesicular main unit. It has, therefore, been mapped separately from the pumiceous texture. Pumiceous perlite is usually light gray but may be buff.

During exploration, near surface pumiceous perlite is difficult to core drill. In the field, the more compacted pumiceous varieties of perlite—shardy—are characteristically difficult to sample because they tend to powder when struck by a geologist's pick and much of the energy is absorbed rather than expended in breaking a chip off the outcrop.

Granular

This texture is found adjacent to and deeper than pumiceous perlite in the emplacement model. It is more dense than the overlying textures, has a “sugary” or saccharoidal appearance, and commercially is highly satisfactory from the milling, classification, and expansibility standpoints. It cores well during drilling and blasts easily during mining. Color usually is buff but varies from gray to brown. It often displays flow banding.

Classical

This is the typical pearl gray material with “onionskin” concentric parting. Classical texture also may be dark gray to black. The name is derived from the classical description of perlite in the literature (Johannsen, 1939). Classical perlite is found stratigraphically below the granular perlite in the dome. Obsidian, whenever present, is always encased in classical perlite, lending substance to the theory that perlite is formed from the hydration of obsidian. The concentric rings around each obsidian nodule were probably formed as the result of volume increase due to the hydration which ad-

vanced only as far as the perlite-obsidian interface. Toward the interior of the flow, the amount of obsidian in classical perlite tends to increase. Also found in perlite deposits are a rhyolitic or felsitic core, flow breccia, and other materials and structures associated with volcanic flows and domes.

In addition to obsidian which may contain what have been identified as tridymite inclusions, often such nonexpandibles as quartz, feldspar, biotite, magnetite, and other accessory minerals as well as products of devitrification, may be present.

Using the No Aqua deposit as a model, Whitson (1982) has expressed, in cross section, the lithologic zonation of these described textures.

DISTRIBUTION OF DEPOSITS

Perlite deposits are restricted to Tertiary or younger volcanics of rhyolitic composition. Because rhyolitic glasses are unstable, they devitrify with age. Very young acidic volcanics have not had sufficient time to hydrate; hence they are still essentially obsidian and not expandible within the temperature range of perlite. There is a belt of Tertiary and Quaternary rhyolites that begins in Iceland, extends south into Ireland, Scotland, through the Massif Central of France into some of the Aegean Islands, through Sardinia and mainland Italy and farther south into Morocco, Algeria, and into South Africa. A Pacific belt splits, with a western limb extending through Japan, the Philippines, China, New Zealand, and Australia. The eastern part of the circum-Pacific belt extends from Alaska (Plafker, 1963) through western Canada, down through the western United States into Mexico, and emerges in parts of the Andes in Chile and Argentina.

North America

While perlitic occurrences have been noted in Alaska and western Canada, the continental United States has the largest known reserves and commercial production in the world (Jaster, 1956; Meisinger, 1985).

In the United States, perlite deposits are confined to the western states. New Mexico accounts for the major share of US production, with substantial deposits at No Agua, Socorro, Grants, and smaller occurrences in the southwest part of the state. Arizona, Nevada, and California have substantial deposits with Idaho, Colorado, Utah, Oregon, and Washington reporting lesser occurrences.

Mexican perlite is centered in the state of Sonora.

South America

Argentina is the major source of South American perlite with most deposits in Salta Province. The only other significant South American deposits are in the Laguna de Maule area of Chile.

Europe

Greece is the largest western European producer of perlite. Major production comes from the island of Milos. The Greek islands of Kos and Lesbos in the Aegean Sea also have commercial grades of perlite from which there has been some production. Numerous other Greek islands contain perlite.

Turkey has substantial reserves of high quality perlite in the western part of the country. There are also occurrences in central and eastern Turkey as well.

Italy is an important source of perlite with the most important deposits located on the island of Sardinia near the town of Uras (Carta, 1976). Perlite is mined on the island of Ponza.

In eastern Europe, Hungary (Perlaki and Szoor, 1973) and the Soviet Union are significant producers of perlite (Rudnyanszky, 1978). Bulgaria, Czechoslovakia, and Yugoslavia have smaller but growing industries (Vladimirov, 1975).

Iceland has a commercially challenging but as yet unproductive perlite deposit at Priest Mountain (Prestahnukur), located about 100 km northeast of Reykjavik. The remoteness of the deposit, the relatively high concentrations of obsidian, and the short four-month mining season offset the otherwise good quality of perlite in many parts of the mountain. A smaller occurrence at Lodmundarfjordur has been investigated, but the location and quality do not justify commercial consideration.

Northern Ireland did at one time have limited production from deposits in the Sandy Braes area of County Antrim.

Small deposits in France and Germany are devitrified or have not been economical to mine.

Africa

Africa has commercial occurrences of perlite at Nxwala Estate, Zululand, and in the Lemombo Mountains, both in northern Natal, South Africa (Coetzee, 1976).

Asia

Japan is the most significant producer of perlite in Asia, which because of the volcanic nature of the islands has numerous perlite deposits. Dominant among these are deposits at Kitakata, Ippongisita, and at Arita. Other deposits are located at the Kushiro prefecture of Hokkaido; at Akita; in Yamagata and Osaka; in Yamaguchi; and in Kumamoto and Fukuoka.

New Zealand has a substantial deposit at Kenlieth and several other deposits have been described (Thompson and Reed, 1954). A large deposit is located on Great Barrier Island, located a few miles off the east coast, northeast of Auckland. Perlite also occurs in Queensland, Australia, and in the Philippines on Luzon Island.

In summary, deposit occurrence worldwide corresponds with island arc and continental volcanism related to plate boundary movement or oceanic spreading center volcanism (Breese and Piper, 1985).

EXPLORATION

Exploration for perlite is restricted to those areas of rhyolitic volcanism between Tertiary and Quaternary age. Any glassy rhyolites of earlier than the Tertiary age have long since devitrified and are not of commercial interest. Younger acidic volcanics will not as yet have hydrated from obsidian. Perlite is recognized in the field by its characteristic appearance, whether it be a rather light gray pumiceous to classical onionskin or the gray to buff granular texture. The presence of marekanite or obsidian nodules (*Apache teardrops*), while detrimental in commercial perlite, are a good field indicator that the prospector may not be far from "pay dirt." Once grab samples have been taken from outcrops or shallow trenches, and upon receipt of encouraging test results, the next step includes the careful mapping of the dome or flow. Careful field work should ascertain the nature and distribution of rock textures and identify other such features as flow banding, joint systems, faults, etc.

The next step, diamond core drilling, is one in which considerable difficulty may be encountered. The friable nature of some perlitic textures, together with fracturing and jointing, may result in poor core recovery. Often only sludge samples can be obtained. In many cases, such mechanical difficulties as hung bits, lost drill steel, and loss of circulation

of drilling fluid may be encountered. Such problems can be minimized with the use of a triple tube wire line core barrel and NQ size core. On some occasions and in less accessible terrain, portable drilling equipment will produce adequate results and often can furnish information not otherwise attainable. The spacing between drill holes and the intervals into which the core is to be split for testing depends on the variability of quality. In many occurrences, variability is so great that the economics of the matter determines the closeness of the drilling and sampling pattern. In general, multistage drilling programs, in which drilling is begun on wide spacings, then tightened up in subsequent stages, are most economical in time and costs. A preliminary indication of quality, when determined in the field, is useful in the exploration for perlite. This can eliminate the shipping of worthless samples back to the laboratory. Whether a crude perlite sample is worth laboratory testing can be ascertained by a petrographic examination for percent contamination, refractive index of the glass, and other criteria (Kadey, 1963).

Geophysical methods had not heretofore been used to any extent in the exploration for perlite deposits. Recently, however, there have been some encouraging results using seismic methods (R. Breese, Manville Corp., personal communication). For the interested reader, the Perlite chapter in the 5th edition of *Industrial Minerals and Rocks* contains a comprehensive treatment of this commodity (Kadey, 1983).

20. Phosphate Rock

M. F. DIBBLE

Phosphate rock refers to commercial concentrations of apatite which occur in both igneous and sedimentary deposits. The quality of marketable phosphates has historically been based on the content of tricalcium phosphate, $\text{Ca}_3(\text{PO}_4)_2$ or "bone phosphate of lime" (BPL). The concentration in igneous rock deposits and chemical processing facilities is more generally referred to as percent phosphorus pentoxide (P_2O_5), which is equal to BPL times 0.4567.

The principal mineral found in igneous deposits is fluorapatite, $[\text{Ca}_{10}(\text{PO}_4)_6\text{F}_2]$ which in its pure form contains about 42.2% P_2O_5 (92.2 BPL) and 3.8% fluorine. Phosphate rock mined in the United States is found exclusively in sediments. The specific mineral found in these sedimentary deposits is francolite, a carbonate fluorapatite, of the general formula $[\text{Ca}_{10-x}\text{Na}_x\text{Mg}_y(\text{PO}_4)_{6-x}(\text{CO}_3)_x\text{F}_{0.4x}\text{F}_2]$ (McClellan) that can contain up to 2.0% molecular CO_2 .

Total world production of phosphate rock products was approximately 158 Mt in 1987. Estimated US production for 1988 is 46 Mt, of which Florida will provide 34 Mt or 74% (Stowasser, 1988). Over 85% of the total phosphate rock mined is used for fertilizer products, either as direct application or the manufacture of upgraded products. Of the phosphate mines in the US, 27 of the 28 are open pit.

SEDIMENTARY PHOSPHATE RESOURCES

Nearly 80% of the total phosphate rock mined in the world is pelletal in form and is found in sedimentary deposits. These francolite pellets are of marine origin and have been found in sedimentary rocks ranging in age from Proterozoic (Precambrian) to Holocene (Cathcart). Many theories have been postulated as to the origin of these types of deposits. It appears that the areas of deposition, because of their scope, had to be open to oceanic water circulation for long periods of time. In general, "phosphorite precipitation took place as the cold, chemically supercharged and somewhat toxic upwellings moved across the shallow platforms and into coastal environments. The biologically stressed shallow-water environments received the bacterially precipitated microcrystalline phosphorite mud or microsporphorite, as well as the other biologically produced phosphate grains" (Riggs, 1978). Depending on the energy level locally, some of these muds were aggregated into pelletal forms as they were reworked by submarine currents, rivers/streams, wind, or a combination of any or all of these. The quantity of francolite in these type deposits can vary from less than 3.0 to an excess of 38% P_2O_5 .

Marine formations that are phosphatized can cover very large areas such as the Phosphoria Formation in the western United States. This formation is of Permian age and covers an area in excess of 349 623 km^2 (135,000 sq miles). Thickness varies from a few millimeters (inches) to many meters (feet) and phosphate content ranges from 16 to 36% P_2O_5 . This formation has been mined for many years from outcrops along a 724-km (450-mile) long belt.

COMMERCIAL SEDIMENTARY DEPOSITS

Central Florida has been a major source of pelletal phosphates since the discovery of the "Land Pebble Deposits" in the 1880s. This rock was originally deposited during the

mid to late Miocene. The present commercial phosphate production of the Central Florida District is the result of the reworking of this rock during the Pleistocene age. This consisted of weathering of unconsolidated pellet phosphorite beds, leaving residual concentrations of francolite pellets. Subsequent high energy sedimentary action resulting from fluctuating sea levels cyclically reworked and redistributed these deposits. Particle enrichment also occurred because of supergene alteration. This constant reworking caused the intermingling of enriched phosphate pellets with silica sand, skeletal land and sea animal remains, and clays.

The Central Florida District covers an area of about 1812 km^2 (700 sq miles). The commercial mineral zone, locally called matrix, ranging from 0.9 to 7.6 m (3 to 25 ft) in thickness, is covered with 3 to 14 m (10 to 45 ft) of overburden. The upper part of the Central Florida District occasionally contains a lateritic leached zone with a high concentration of uranium-bearing aluminum phosphates. Historically, the pelletal pebble fraction coarser than 1.0 mm has been of high enough grade to be screened, washed, and sold as product. The -1.0 mm pellets, which occurred intermixed with silica sand and clays, were formerly discarded as debris.

The development of two-stage anionic/cationic froth flotation in the late 1930s led to the recovery of the -1.0 mm +100 μm phosphatic pellets by removing the silica (insol) waste. Concentrates occasionally exceeded 80% BPL (37% P_2O_5) from these high grade deposits. (BPL is more commonly used by miners in this district.) The development of the two-stage flotation process made possible the successful reprocessing of the old debris dumps resulting from earlier pebble mining.

During the glory years of mining in this district, a general rule of thumb for this matrix was that it was composed of one-third pelletal phosphate, one-third silica sand or insol, and one-third clay. As mining has depleted higher grade ores and moved southward toward the fringes of the Central Florida District, pebble and flotation-sized pellets are less enriched and contain higher concentrations of carbonates. Typical pebble grades of the 1950-1960s of 68% to 74% BPL (31.1 to 33.9% P_2O_5) are now more likely to be 62% to 68% BPL (28.4 to 31.1% P_2O_5). Flotation concentrates now range from 66 to 72% BPL (30.2 to 32.9% P_2O_5) from the high 70%'s (+35% P_2O_5) in earlier years.

FUTURE CENTRAL/SOUTH FLORIDA RESOURCES

The Hawthorn Group of Miocene age covers most of peninsular Florida with the exceptions of the Ocala Arch and Sanford High. Underlying the Bone Valley Member, Pease River Formation of the Hawthorn Group (Scott, 1985), it consists of impure carbonates with varying concentrations of well rounded phosphate pellets.

Representing a significant, more costly, future phosphate rock resource is a weathered extension of the Hawthorn Group. This formation underlies and extends southward from the Central Florida District. This southern extension can be subdivided into three distinct units. The lowest is predominately carbonate with pelletal francolite particles in-

termingled. The middle unit is a transitional zone with pelletal phosphate particles intermixed with dolosilts and clays. The upper unit is primarily clastics with phosphate pellets, quartz sand, clays, dolosilts, and distinct dolomitic particles.

The upper clastic unit is further subdivided into two zones. The upper zone somewhat resembles typical Central Florida District rock with some exceptions. The matrix grade is lower, the enrichment of the pellets is less, and the ratio of $\text{CaO}:\text{P}_2\text{O}_5$ is higher, approximately 1.55 (the higher number usually reflects greater sulfuric acid consumption when the rock is acidulated). The $-100\text{ }\mu\text{m}$ clay slimes are higher in quantity and the pebble fraction poorer in both quality and quantity. The MgO content of normal concentrate is significantly higher than what is found in the Central Florida District. This upper zone is not found throughout the southern extension and varies significantly in thickness.

The lower zone is quite different from the upper. The presence of dolomite produces an unacceptably high level of MgO when conventional phosphate concentration methods are used. The coarser individual pellets also contain inclusions of dolomite as well as silica. Carbonates are found as distinct beds and as separate grains intermingled with the pellets. Clays and dolosilts can be found as individual beds and interspersed throughout the matrix section. Pebble and concentrate from most of this lower zone is generally unacceptable for use in a typical wet process acid plant unless there is reduction of the MgO content.

The southern extension is generally considered the logical direction of movement for the existing mining companies and operations when the Central Florida District is depleted in the fairly near future. Development will need to consider both zones as part of a mining sequence to maximize resource recovery. Significant progress has been reported by various investigators (Lawver, et al., 1984) to reduce the dolomite (MgO) content of product from both of these zones.

Table 1 was developed to define the fundamental differences between the traditional Central Florida deposits and the southern extension of the weathered Hawthorn.

The southern extension of the Central Florida District represents a large potential resource, more costly to produce and lower in quality than the present district. Table 1 shows that potential mining costs (per ton of product) should be significantly higher than the Central Florida District because of the sheer magnitude of material that needs to be stripped,

mined, and then replaced during required reclamation. The removal of the dolomite in the concentration step would also add to the product costs. The waste clays, which are roughly 2.5 times the quantity of the Central Florida District per ton of product, will present challenging obstacles in obtaining necessary permits for mining as well as actual disposal.

NORTH CENTRAL FLORIDA PHOSPHATE RESOURCES

Extensive shallow Hawthorn phosphate resources exist east of the Ocala Arch on the North Florida Platform. One company operates two mines near Lake City. This rock has also been reworked but less extensively than the Central District. The alteration and supergene enrichment has been less which has limited the availability of marketable pebble products.

Extensive regional prospecting in north Florida and south Georgia was conducted during the 1960s in the general area of these existing operations. In most cases the quantity of pelletal phosphates was too low, at that time, or was located in areas of great environmental sensitivity.

DEEP MIOCENE DEPOSITS, NORTH CAROLINA

The Miocene was also the most important period in the development of the extensive phosphorites formed throughout the southeastern United States continental margin. These deposits are found from Chesapeake Bay in Virginia to south of Cape Canaveral (Cape Kennedy) in Florida.

One of the more important and proven phosphogenic provinces of these Miocene sediments is the Pungo River Formation. The phosphate-enriched section occurs as highly truncated sequences of multiple depositional units in eastern North Carolina (Riggs, 1986). Cape Lookout High subdivides a large Neogene basin into two regional embayments. The northern or Aurora embayment is the site of one of the largest operating phosphate mines in the United States.

The Aurora phosphate district is one of the shallower, more accessible, occurrences of commercial grade rock in this coastal margin and is mined by open pit. Overburden is partially removed by a dredge stripping the upper 11 m (35 ft). After dredging a specific area, the phosphate-rich Pungo River Formation is dewatered by depressurizing the underlying Castle Haynes Eocene Limestone Formation. The overburden remaining after dredging, from 11 m (35 ft) down

Table 1. Differences Between Central Florida Deposits and the Southern Extension

	Central District	Southern Extension
Matrix thickness	Average 25 ft	Up to 65 ft
Matrix grade, $\text{P}_2\text{O}_5\%$	11.4 to 13.7%	5.5 to 8.2%
Matrix yards per ton product	3.0 to 4.0	4.0 to 6.5
Matrix & overburden, tons moved per tons prod.	7.5 to 12.0	12.0 to 14.0
Tons prod. per acre-foot mined	400 to 600	200 to 400
Pebble product, $\text{P}_2\text{O}_5\%$	10% of matrix 28.4 to 31.1 direct salable	5% of matrix 18.3, upgrading required
Flotation product, $\text{P}_2\text{O}_5\%$	30.1 to 32.9 using standard double flotation	29.2 to 31.5, req. Additional dolomite removal stage req.
Product $\text{CaO}:\text{P}_2\text{O}_5$	1.50 to 1.52	1.55 to 1.57
Product $\text{MgO}\%$ content	0.2 to 0.5%	0.7 to 1.3%
Combined iron and aluminum oxide	1.4 to 2.6%	2.0 to 3.8%
Waste material	Quartz sand and clay	Sand and clay plus dolomite particles, marl
Tons waste clay per ton of product.	0.9 to 1.1	2.0 to 2.5

Metric equivalents: yard $\times 0.914$ = meter; ton $\times 0.907$ = tonne; foot $\times 0.305$ = meter; acre-foot $\times 1233$ = cubic meter.

to about 28 m (93 ft), is stripped by large dragline and the spoil dumped into the adjacent mined-out pit. This same dragline also mines the matrix section, which can range from 11 to 12 m (35 to 40 ft) in thickness, and stockpiles it on top of the dredged surface. A smaller dragline then reclaims the stockpile and dumps the matrix at a portable pumping station to be slurried by high pressure water. The slurried matrix is then pumped to the process facility (Hird, 1988).

A program is underway to replace the dredge and remove the upper overburden by use of a bucket wheel excavator. This improves the operational efficiency by moving upper waste material at natural percent solids and opens up the area for the dragline more effectively. High solids content allows more efficient transport of this overburden with a conveyor belt system (Breza, 1987).

The francolite pellets at this deposit show evidence of only localized reworking. The product tons per acre is much higher than in the Central Florida District and can approach 32 to 36 Mt (35,000 to 40,000 tons) per acre. The flotation feed grade is also much higher and finer in mesh size than from rock presently mined in Central Florida. No commercial pebble product is produced.

The final product grade obtainable is about 29.7 to 30.7% P_2O_5 . The $CaO:P_2O_5$ ratio is close to 1.60 due to the lack of supergene enrichment. Concentrates from this rock have a lower combined iron and aluminum oxide content compared to Central Florida concentrate. The rock also contains a high concentration of organic carbon that can be removed by calcination if necessary.

ALTERNATIVE DEEP MIOCENE RESOURCES

South of the Cape Lookout High is the Onslow embayment, which underlies the continental shelf in Onslow Bay. Two significant phosphate rock occurrences have been discovered by shallow drilling and surface sampling. Seismic data has indicated that substantial additional resources may be present and extend well beyond the areas sampled.

Moving further south is the Beaufort High (Riggs, 1986) that apparently provided the same conditions for phosphate rock deposition as the Cape Lookout High. Low concentrations of phosphate minerals have been observed west of this High in the Beaufort, SC, deposits (Woolsey, 1977). South of this High occurs the Chatham, GA, embayment where seismic data has indicated a substantial Miocene section (Riggs, 1986).

DEEP MIOCENE DEPOSITS, NORTHEAST FLORIDA

A major Miocene resource has been partially defined within the Jacksonville, FL, Basin. The deposition of phosphorites appears to be controlled by the presence of the Sanford High. The magnitude of this resource is unknown since only the western and southern end of the deposit has been roughly defined. The JOIDES deep drill core hole, J-1, drilled on the continental shelf 45 km (28 miles) east of Jacksonville, indicated a Miocene thickness of at least 79 m (260 ft), beneath a cover of 18 m (60 ft) of Plio-Pleistocene sediment (Riggs, 1986). Onshore drilling in this basin indicated commercial thicknesses and grades of Miocene phosphates at least 80 km (50 miles) to the southwest of J-1.

Extensive core drilling conducted during the late 1960s indicated that a sizable primary phosphate resource exists north of St. Augustine, FL. Subsequent drilling further defined this resource and indicated that it should project eastward under the continental shelf for some distance (Brown, 1979). If continuity were established between the landside

phosphates, the J-1 hole, and an eastward extension, this could represent a substantial phosphatic resource.

The landside deposit consists of five to six different lithologic units. The lowest two units are referred to as "D" and "E" with the lowest, E, representing the largest potential source of phosphate rock. This E zone appears to be always present throughout the phosphogenic environment and can vary from 1.5 to 11 m (5 to 36 ft) in thickness. The top of the D zone, when present, occurs at depths from 55 to over 91 m (180 to over 300 ft) below the surface. The two zones are separated by a barren clay member and the E zone is usually capped with dolomite of differing degrees of hardness. This barren zone can vary in thickness from 0 to 4.6 m (0 to 15 ft). Overall the E zone feed sized material ($-600 + 74 \mu m$) will usually exceed 18.3% P_2O_5 . There is no pelletal pebble-sized particles present. The upper D zone is lower grade than E, and ranges from 9.1 to 16% P_2O_5 . Some reworking is evident in the D zone as indicated by water-rounded silica sand particles and less clay than the E zone.

The product grade indicated from experimental borehole mining tests shows many similarities to the product obtained in North Carolina (Davis, 1982). The Jacksonville Basin concentrate has a slightly higher P_2O_5 , lower $CaO:P_2O_5$ ratio, lower organic carbon content, lower combined iron and aluminum oxide content, and equal to slightly higher MgO content. The combination of the minor elements present (sometimes referred to as the minor element ratio or MER), including iron and aluminum oxide plus the MgO divided by the P_2O_5 content, is from 0.055 to 0.060.

DEEP MIOCENE PHOSPHATE ROCK POTENTIAL EXTRACTION TECHNIQUES

Most of the deep Miocene deposits, other than the relatively shallow North Carolina Pungo River deposits, are too deep to be mined by conventional open pit methods. The Jacksonville Basin rock, for example, is covered by recent to Plio-Pleistocene sand and shell hash from 18 to 24 m (60 to 80 ft) in depth. This is followed by clay, sandy limestone, and interbedded clay and shells. Below this and consistent throughout that mineral province is a massive dark green rubbery clay section that is at least 18 m (60 ft) in thickness. Underlying this clay section is a dolomitic rock that can range from 0 to 2.4 m (0 to 8 ft) in thickness, with varying degrees of hardness, that caps the D zone phosphate rock (Brown, 1979).

Experimental borehole mining tests to slurry mine phosphate rock from this and North Carolina deposits were made during the 1960s (McKelvey, 1985). In 1980, a limited program with improved technology, was conducted in conjunction with the US Bureau of Mines in the Jacksonville Basin (Savanick, 1985). In 1984-1985 additional tests conducted by private companies near that site were encouraging and demonstrated that this rock could be mined successfully if a flooded cavity environment was maintained (Dibble, 1985). The waste clay resulting from mining was reinjected back into the cavities. The nature of the overburden, at that location, eliminated the need for casing below the upper contact of the dense clay member. The casings used in the latest tests were pulled and could have been recycled repeatedly.

Borehole mining technology is still in its embryonic stage. Information gained during the most recent borehole mining tests indicated several areas where improvements were possible, making this concept more economically attractive (Dibble, 1987). Deep Miocene phosphate resources found both on land and under the continental shelf represent the largest potential major phosphate rock source. Borehole min-

ing technology will need to be developed to recover a major portion of this resource. By proving this technology to be economically competitive with conventional deep open pit mining or dredging for the offshore rock, the United States agricultural sector could remain free from dependence on foreign phosphate rock sources.

FERTILIZER PRODUCTION—FUTURE SUPPLIES

The Central Florida District rock have been the standard of comparison for new sedimentary phosphate deposits. Chemical processing plants for fertilizer manufacture have traditionally been geared to use this rock. Adjustment to plant operations has been necessary as mining has moved southward and rock quality has diminished. Rock supplied to these same plants from the deep Miocene deposits would probably require additional plant modifications. Because the deeper Miocene deposits have not been extensively reworked, the rock quality throughout a given deposit is very consistent. A process facility geared to use this type of rock would have very stable operations because of this inherent consistency.

The Central Florida deposits are being rapidly depleted. The location of the very large western Phosphoria deposits, with their high mining, processing, and transportation costs to the consuming market, does not indicate that they can be used to replace much of this depleted rock. The United States, in order to maintain its present fertilizer production capacity with domestic rock into the 21st century, needs to make substantial changes from traditional sources. Either production must be greatly expanded in North Carolina, the processing technology must be commercialized to mine the Central Florida southern extension of the Hawthorn, or the mining technology must be developed to recover the other deep on- and offshore Miocene deposits.

To determine the direction the US fertilizer industry must take, these two major future sources of rock need to be compared. This comparison must assume that eventually the metallurgical problems will be solved to commercially process the southern extension of the Hawthorn Formation. It will also be assumed, for the sake of comparison, that the technology necessary for deep Miocene deposit mining can also be developed. Many other factors besides technical ones will influence the direction taken, so Table 2 can only serve to illustrate fundamental differences between these two sources.

FUTURE SOURCE COMPARISONS

The deeper Miocene phosphate rock has many apparent advantages over the southern extension Hawthorn rock as illustrated in Table 2. In addition, the borehole mining technology causes a minimal disturbance of the surface and almost immediately upon completion of mining, the surface would be available for other purposes. This is more environmentally acceptable than open pit mining followed by required reclamation. In the event that the offshore deposits could also be mined, less environmental damage would occur when compared to dredging. The operational concept calls for mining to start from the bottom of the mineral section and to work upwards. Dredging works the opposite since the overburden has to be physically relocated, and then the phosphate. Stirring up the fine sediments with a dredge could cause some turbidity that may not be environmentally acceptable (Woolsey, 1987).

The deep Miocene phosphate deposits do have some disadvantages when compared with the southern extension rock. Most of the major fertilizer plants are located convenient to the Central Florida deposits. The open pit mining technology

using draglines is well proven and has been relatively cost effective. Mining by large draglines recovers a significantly higher percentage of the available phosphate rock than what can be expected with a borehole system. Mining tradition in the region already exists because of present mining in the Central Florida District. Although environmental pressures against open pit operations are already high and intensifying, phosphate mining has historically provided substantial financial contributions to the region.

There is no phosphate mining experience in areas where the deep Miocene deposits occur except in North Carolina. Near shore lands are becoming more valuable, and it will become increasingly more difficult, as large land holders such as timberland interests are broken up, to put together large enough tracts to support mining ventures. This may force a greater emphasis, in the long-term, on the offshore Miocene deposits, which may be more costly to produce than the deeper onshore deposits.

EXPLORATION METHODS

The limits of the Central Florida District have been well defined for many years. A flurry of exploration activity in the 1960s also helped define the general limits of the southern Hawthorn extension. Exploration usually consisted of reconnaissance drilling using a pattern of one to four core holes per square mile. Core samples were then taken from the matrix section encountered and divided into lithologic units or splits and carefully logged by the geologist.

Samples are obtained for moisture and bulk density calculations. Each split is washed in the preparation laboratory which removes the clay fraction, usually $-100\text{ }\mu\text{m}$, through cycloning or screening. The coarse fraction is also separated at approximately 1.0 mm size to determine the nature or quantity of the pelletal pebble fraction. The remaining material is the feed-sized fraction which is processed by flotation in the laboratory cell. Generally these splits are processed in accordance with the same flowsheet used in existing plants of that specific area. In the case of cores from the southern extension, additional concentration steps can be made to upgrade the product quality.

Calculations are made from the results obtained in processing core samples to determine bulk density, product distribution, product quality, clay content, product tons per acre, and tons per acre-foot. An acceptable reconnaissance hole is usually followed by a denser pattern that may eventually end up with as many as 16 holes per 40 acres. Mine production plans are usually developed with this hole density in the Central Florida District.

Most of the large tracts of land existing in the southern extension have already been acquired by mining companies or land speculators knowledgeable of the phosphate mining industry. Large tracts are usually optioned and then drilled. The early definition of the district was made from reconnaissance drilling from roadways and other rights-of-way.

Exploration for the deeper landside Miocene deposits is much more complicated than prospecting a known, relatively shallow deposit. The geologist in charge of an exploration project must have a good working knowledge of the stratigraphic sections to be encountered. He should also know the interrelationships of the various southeastern highs and basins and the conditions leading to phosphate rock deposition.

One of the best screening methods to determine the presence of these Miocene phosphates is the gamma-ray logger. Much of the early work in defining the North Carolina

Table 2. Differences Between the Southern Extension and Miocene Deposits

	Southern Extension	Miocene (north FL-NC)
Matrix & overburden tons moved per tons prod.	12.0 to 14.0	1.75 to 2.5 (o'b not moved, drilled through with B.H.)
Matrix grade, P ₂ O ₅ %	5.5 to 8.2	13.7 to 22.8
Tons prod. per acre-foot mined	200 to 400	600 to 1,000
Pebble product	5% of matrix, 18.3 P ₂ O ₅ %.	Not present.
	Upgrade?	
Flotation product, P ₂ O ₅ %	29.2 to 31.1 req. Dolomite removal	30.6 to 31.1 Single-stage flotation possible.
Product CaO:P ₂ O ₅	1.55 to 1.57	1.50 to 1.55
Combined iron and aluminum oxide	2.0 to 3.8%	0.9 to 1.1%
Product MgO	0.7 to 1.3%	0.65 to 0.85%
Product organic carbon	Low	Up to 2.0%
Minor element ratio	0.10 to 0.13	0.055 to 0.065
Tons waste clay per ton product.	2.0 to 2.5	0.4 to 0.6
Reclamation required	Total surface of mined area needs to be reclaimed	No surface disturb.; waste clay and sand injected back into mined out cavity

Metric equivalents: ton \times 0.907 = tonne; acre-foot \times 1233 = cubic foot.

resource was in gamma logging water wells (White, 1984). The Jacksonville Basin exploration work found that the initial dolomite section overlying the D zone phosphate rock had a very strong gamma-ray kick. The phosphate rock zones below this cap closely reflected the concentration of francolite pellets present by the magnitude of the gamma count. The dolomite always found under the phosphate sections also had a sharp kick at the top and bottom. Once below the Miocene dolomite into the Eocene limestone of the Floridian aquifer, the radiation was very minimal.

The landside drilling of these deeper deposits necessitated more careful monitoring of the drilling progress by a competent geologist. The higher costs of drilling these deeper holes mandated that the amount of information collected be maximized. If the depth precluded the possibility of open pit mining, the overlying sections have to be carefully logged to determine their future impact on alternative mining methods such as borehole mining. The individual phosphate sections need to be evaluated to determine capping stability, barren clay sections, dolomite stringers, and the nature of formations separating individual phosphate sections. In all cases, completed drill holes should be gamma-logged to coordinate depths and define the interfaces of the marker horizons.

The processing of cores obtained in deeper Miocene deposits is basically similar to that practiced in the Central Florida Hawthorn extension. The geologist should carefully log the lithologic features and define the presence of barren clay stringers or beds. If borehole mining proves to be the only applicable mining method, the nature of the clay zones could have a profound effect on the mining recovery and on the eventual surface processing facilities.

For example, in open pit mining of phosphate rock with a dragline essentially all of the matrix section is mined and slurried for transport to the washer/concentrator. All the clay contained in the mined section is eventually broken up and subsequently sent to a clay (slimes) storage area at a very low percent solids. The results would be somewhat similar in dredging but possibly to a somewhat lesser degree. The effect of borehole mining would be much different as the clay sections are much harder to slurry than the higher grade phosphate sections. A fairly high percentage of this resistive clay will not be slurried but will remain in the cavity as large lumps. The barren clay lumps that do report to the surface could easily be screened out and separated at the mining site. The borehole test programs in both North Car-

olina (Morrow, 1980) and north Florida reported less clay in the slurry than was indicated from the analysis of the drill cores. In the most recent tests at least one-third of the total clay present did not slurry and remained as coarse clay lumps (Dibble, 1985).

Since the deeper Miocene deposits are essentially primary in origin and have not been reworked, they are relatively consistent over a fairly large area. The drilling density of the existing North Carolina deposit does not need to exceed one hole per every 60 acres. The lack of reworking in the Jacksonville Basin, with the indicated consistency over large areas, should not require a density of more than one hole per 80 acres.

The offshore Miocene deposits will be much more expensive to prospect than the onshore occurrences. Seismic work conducted in Onslow Bay, NC (Riggs, 1987), indicated that this tool can be used to broadly define the presence of Miocene age formations at depth. To date there has not been any deep drill holes in that area to provide correlation. Shallow vibra-core holes drilled in this area indicated the possible top of phosphate-containing Miocene beds. The phosphate materials found in these samples had been diluted by biogenic debris and rock fragments resulting from ongoing erosion typical of that environment.

The ability to drill deep core holes in these basins will require a stable drilling platform. The high cost of conducting such a program eliminates most private companies from sponsoring such a project. Additionally, the lack of assurances to the potential sponsor of eventual ownership of the mineral found makes such exploration efforts difficult to rationalize. The development of these offshore resources will not be done in the near future unless such exploration efforts are funded by federal or state agencies.

Active efforts are needed to develop borehole mining technology and define these large offshore phosphorites. Without this effort, the southern extension of the Hawthorn may be the only future source of domestic phosphate rock developed. Unfortunately, it is questionable whether this higher cost rock will be able to compete economically with the abundant sedimentary phosphate rock from Morocco (Stowasser, 1985). The depletion of the Central Florida deposits could turn the United States into a net importer of phosphate rock to meet domestic requirements while the enormous, deep, potentially lower cost Miocene resources remained relatively undeveloped.

21. Pyrophyllite*

Most technical and statistical data published on pyrophyllite relating to production figures, uses, markets and sales, have in the past traditionally linked the mineral with the talc and soapstone. This is due to several common superficial physical properties resulting in substitute uses and applications. However, these minerals are not similar in chemical composition and do not generally occur in a similar geological environment.

Pyrophyllite now stands on its own in the marketplace—particularly in ceramic applications—due to the combination of excellent heat shock and creep resistance properties of the mineral. The increase in pyrophyllite use in the field of ceramics indicates the continuing realization of these marked unique properties. Several new fields of ceramic applications, previously the preserve of high-alumina materials, have been developed on the intrinsic properties of pyrophyllite.

Pyrophyllite is an aluminum silicate with the molecular formula of $\text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot \text{H}_2\text{O}$. It would be more appropriate to group pyrophyllite with such materials as kyanite, diaspore, andalusite, and certain high-alumina clays in relation to its general applications (Stuckey, 1928). These materials all have good heat shock resistance properties at high temperatures and are widely used for the manufacture of refractories. For those reasons, they are interchangeable in some applications. Pyrophyllite also has many uses in nonceramic applications, the most important to date being as a substitute for talc in fillers.

The major pyrophyllite mining operations are located in the US, Japan, Korea, Canada, and Australia, where the mineral is widely used as a raw material for general ceramic, mineral filler, and dilutant applications.

COMMERCIAL APPLICATIONS

Pyrophyllite was first used in the last century for lining stoves and fireplaces, and also in the carving and polishing of ornamental objects. The rise in industrial demand for new products and applications resulted in the introduction of pyrophyllite as an alternative, mainly for talc and soapstone. Industrial filler applications followed for paint, paper, cosmetics, rubber, pesticides, crayons and pencils, and bleaching soap.

The first use of pyrophyllite in ceramic applications was prior to World War II in the manufacture of ceramic cladding tiles in the US. This was followed by the production of kiln furniture refractories and whiteware when pyrophyllite was offered by suppliers in North Carolina as an alternative to some local clays.

The largest tonnages of pyrophyllite used today are in refractory linings in steel ladles in Japan. The consumption of pyrophyllite in Japan is second only to clay and chamotte among refractory raw materials used. Recently this technology has been adopted in Australia. Japanese and Australian practice has resulted in appreciable technical and economic benefits, particularly when pyrophyllite is used in combination with zircon. The potential growth for this application is substantial if US and European steelmakers follow.

Investigation and research into the properties of pyrophyllite determined the following main advantages of pyrophyllite-based ceramics: high corrosion resistance for molten iron, steel, and slags; good heat shock resistance; good indices of deformation under load and hot creep resistance (refractories); and increase in mechanical strength of whiteware products promoted by a better distribution of mullite in finished products (also obtained at lower firing temperatures than normally required in production of triaxial ceramics). White cement clinker formulation based on pyrophyllite generally has an advantage of a low iron content when compared with batches made up from silica and clay mixtures. A lower temperature of clinker sintering of batches is possible due to the higher reactivity of the pyrophyllite. White road aggregate made from calcined pyrophyllite rock exhibits high polished stone values (PSV), high aggregate impact values (AIV), and high luminance factors (LF).

These intrinsic properties of pyrophyllite disclosed potential ceramics uses which subsequently have been commercially exploited in industrial countries around the world in contact refractories for lining steel ladles; kiln furniture for tunnel kilns; refractory mortars; ingredients for vitreous china, stoneware, chinaware and wall tile bodies; manufacture of white cement; calcined pyrophyllite for use in white road-making aggregate; and refractories for use in furnaces, melting ceramic and enamel fritts.

GEOLOGY

Mineralogy

Pyrophyllite is an hydrated aluminosilicate which has a phyllosilicate sheet or layer structure. This structure consists of two (Si_2O_5) nets between which are interposed a layer of groups of octahedral aluminum cations surrounded by oxygen and hydroxyl anions. The crystalline system of pyrophyllite is monoclinic.

The structural formula of pyrophyllite, $\text{Si}_4\text{O}_{10}\text{Al}_2(\text{OH})_2$, also could be presented in the oxide form $4\text{SiO}_2 \cdot \text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$. The centesimal theoretical pure composition of pyrophyllite is SiO_2 , 66.7%; Al_2O_3 , 28.3%; and H_2O , 5%.

Pyrophyllite ore bodies often contain the following characteristic mineral assemblage: diaspore, corundum, pyrophyllite, kaolinite, alunite, silica (quartz), sericite, and montmorillonite (Iwao, 1953). A diagrammatic representation of Iwao's concept of mineral segregation within hydrothermal deposits derived from volcanic rocks in Japan is given under "Classification of Deposits." The mineral assemblage at Pambula, NSW, Australia is somewhat similar: diaspore, chlorite-cookeite, pyrophyllite, kaolinite, chalcodony (quartz), and sericite.

Diaspore occurs commonly as a minor constituent in most pyrophyllite deposits. Less than 20% of the samples contain diaspore, with minor amounts of kaolinite in the massive pyrophyllite zones.

Chlorite-cookeite occurs near the central shear zone of the ore body where quartz and sericite are virtually absent. Appreciable quantities of chlorite and, to a lesser extent, diaspore are associated with the pyrophyllite. The chlorite has a dioctahedral X-ray diffraction pattern and is characterized by abundant aluminum and a small significant lithium content, and has been identified as the mineral cookeite ($\text{Al}_{0.93}\text{Fe}_{0.02}\text{Mg}_{0.02}\text{Li}_{0.81}\text{Al}_{0.74}\text{Si}_{3.26}\text{O}_{10}(\text{OH})_8$).

*Excerpt from Cornish, B.E., 1983, "Pyrophyllite," *Industrial Minerals and Rocks*, 5th ed., Vol. 2, S.J. Lefond, ed., AIME, New York, pp. 1085-1108.

Pyrophyllite occurs as a solid mass varying in color from green to yellow to white. It has physical properties similar to talc. The mineral has a low hardness and a good mechanical strength.

Kaolinite often occurs in associated shear zones and is probably developed during a retrogressive stage, possibly by the silicification of diaspore but more likely from cookeite through the loss of lithium.

Chalcedony appears throughout pyrophyllite ore bodies as in Australian and Korean deposits, with the exception of the pure pyrophyllite lenses ranging in size from large inclusions of quartz to small grains.

Sericite occurs in solid lensoid masses similar to pyrophyllite and can generally be separated by visual inspection. The percentage of alkalis in sericite lenses is in the range of 0.05 to 5%. Sericite is primarily a potash alkali.

Classification of Deposits

A twofold classification of pyrophyllite deposits is evident based on geological mode of occurrence.

Hydrothermal Deposits: These are the most common and are associated with acid-volcanic complexes. Hydrothermal solutions originating within the complex passed along channelways formed by faults or shears and transformed the country rock from rhyolite or feldspar-quartz to pyrophyllite-quartz. Hydrothermal alteration is indicated by dilution of alkali and iron oxide values and abnormally high lithium oxide values. The Pambula pyrophyllite deposit near Eden, NSW, is such an example.

Figs. 1 and 2 show diagrammatic representation of Iwao's (1953) concept of mineral segregation within hydrothermal deposits derived from hydrothermal rocks in Japan showing a hypothetical erosion surface and subsequent surface-exposed mineralogical relationship.

Metamorphic Deposits: These are less common and are found to be associated with metamorphosed volcanic ashes. Pyrophyllite-schist is developed and typically grades irregularly into other schistose rocks. In this case dilution of K_2O values is difficult to explain in terms of isochemical metamorphism. The recording of pyrophyllite-schist near Peak Hill, NSW, is an example of this metamorphic origin.

Principal Producing Countries

Japan: Pyrophyllite was first discovered in Japan in 1797 on Mount Omotoyama, at the site of the Mitsuishi mine of the Shinagawa Mining Co. In the early 1800s, sawn blocks of pyrophyllite were used for carving images and in the manufacture of slate pencils, signature seals, and firebricks.

FIG. 1 Diagrammatic representation of Iwao's concept of mineral segregation within hydrothermal deposits derived from volcanic rocks in Japan. Source: Modified from Iwao (1953).

FIG. 2 Diagrammatic representation of Iwao's concept of mineral segregation. D = diaspore, C = corundum, P = pyrophyllite, K = kaolin, A = alunite, Si = silica, Se = sericite, Mo = montmorillonite. A-A' is a hypothetical erosion surface.

In 1885, deposits in the Mitsuishi district were surveyed by the Imperial Geological Survey, and this work established the existence of abundant reserves of usable quality ore.

The most important pyrophyllite production is in Okayama. This prefecture is near the south coast of southwest Honshu Island, approximately 145 km (90 miles) west of Osaka. Fifty-seven of the 70 mines in Japan are known to have produced various quantities of pyrophyllite. Of these 57 principal mines, 27 are located in Okayama prefecture.

The largest production from Okayama has been from the Shinagawa-Mitsuishi Ohira, Kawabe, and Kato mines. Significant production has also been recorded from the Shinagawa-Makata, Fukuyama, and Kiyotaki mines in Hyogo prefecture. The Shokozan mine in Hiroshima prefecture has also produced significant quantities of pyrophyllite. In Hiroshima and Hyogo prefectures, massive pyrophyllite deposits in rhyolite and porphyry include the accessory minerals diaspore, kaolinite, corundum, pyrite, and alunite.

The second important pyrophyllite-producing area in Japan is in Kanzaki-gun, Hyogo prefecture. Six mines are known in this area, which is located 113 km (70 miles) northeast of Okayama.

Three important mines also exist in the Kinosaki-gun, Hyogo prefecture. These mines occur between the Okayama and Kanzaki districts, in which the largest reserves of pyrophyllite in the world occur.

The Japanese pyrophyllite deposits were formed by the hydrothermal alteration of porphyry and liparite. In Okayama prefecture, pyrophyllite occurs as veins and irregular masses within sedimentary and volcanic rocks. Kaolin accompanies pyrophyllite within the upper parts of the ore bodies, with nodules of diaspore occurring in the central part of the ore mass, and pyrite and marcasite in the lower parts. The deposits were probably formed by the replacement of andesites, shales, agglomerates, rhyolites, and porphyries which were permeated by hot hydrothermal solutions associated with volcanism.

South Korea: Pyrophyllite is mined in two major areas of South Korea, both near the coast in the southern part of the peninsula. The largest production is from the Wan-Do mine at Haenam. Major mines in the Haenam area are the Sungsan, Hwansan, Okmesan, Dae-Do, and Chin-Do mines. The deposits mined are tabular, and are associated in places with diaspore.

The second major pyrophyllite-producing area in South Korea is at Dong Nae where the Nilyang, Yangsan, Kimhae, Pusan, and Kyong-nam mines are worked. The deposits in the Dong Nae area were formed by the alteration of intermediate volcanic rocks including andesite, trachyte, trachytic andesite, and quartz porphyry. The host rocks of the Pusan and Kyongnam mines consist of quartz-porphyry and feldspar porphyry, while trachytic andesite is the host rock in

the Dong Nae, Imgi, and Nilyang mines. Pyrophyllite in the Dong Nae area is thought to have been formed by hydrothermal alteration of volcanic rocks by granite intrusives of Cretaceous age, from which hydrothermal solutions filled fissures in tuffs and volcanics. The Yangsan and Un-Yang granite are thought to be the principal mineralizers in the Dong Nae area. In the Haenam area pyrophyllite deposits resulted from fissure-filling tuffs and rhyolites.

The major reserves of pyrophyllite in South Korea are primarily located at Wan-Do, where inferred ore reserves total approximately 30 Mt.

United States: The production of pyrophyllite in the US is limited to the states of North Carolina and California. Annual US production is approximately 100 kt, and reserves of various grades of pyrophyllite are estimated at 1.5 Mt.

Principal production in the US is in Moore and Randolph Counties in North Carolina. Other occurrences in North Carolina are in Granville, Orange, Alamance, and Montgomery Counties. The North Carolina belt actually starts near the Virginia line and extends across the state through South Carolina to Graves Mountain, Georgia. Other occurrences of pyrophyllite in the US have been reported in the South Mountain area of Pennsylvania and in California.

Pyrophyllite occurs in irregular, lenticular, or bedded deposits. The pyrophyllite deposits of North Carolina occur within rhyolite volcanic rocks and form oval or lenticular bodies up to 152 m (500 ft) wide and several hundred meters (feet) long, located within fracture zones. According to Stuckey (1928) the North Carolina deposits were formed through metasomatic replacement of Precambrian acid tuffs and breccias of both dacitic and rhyolitic composition. Pyrophyllite occurs with quartz and sericite, forming the central part of these lenses and grading outward into impure zones. The bulk of production comes from a few large deposits mined by open-cut and underground methods and used in ceramic filler dilutant and carrier applications.

The other district in the US where pyrophyllite has been produced commercially is in California. Sericitic pyrophyllite is mined in Inyo and San Diego Counties for ceramic applications. The San Diego County pyrophyllite deposit was described by Jahns and Lance (1950). An important deposit called the Pioneer mine occurs in the San Dieguito area northeast of La Jolla and 12 km (7½ miles) from Escondido, the shipping point by rail. The deposits occur in the Santiago Peak volcanic series, which comprises miscellaneous rocks of Jurassic age. The pyrophyllite deposits, which occur within an area of about 2.6 km² (1 sq mile), represent progressive stages in the alteration of the volcanic rocks. Nearly all the pyrophyllite mined has been obtained from open pits in a single mass of high-grade schist 46 m (150 ft) long and 4.6 m (15 ft) wide.

Australia: The main pyrophyllite deposit in Australia is located at Pambula near the deep water port of Eden on the southeast coast of New South Wales. An intrusive and extrusive volcanic assemblage formed in an active tectonic environment during the Upper Devonian period provided the basis for extensive hydrothermal activity and burial metamorphism. This hydrothermal activity associated with the volcanism formed irregular and lenticular mineralization, rich in aluminous phases, by the remobilization and the dissipation of the alkali components of the host rock (Taylor, 1978). Suitability of this host rock and structural competence of the volcanic sheet control the geometry and distribution of the deposits, with optimal conditions favoring large, strongly cleaved, broadly altered lensoid bodies.

It is probable that the mineralization at Pambula origi-

nated by a similar process to the zonal distribution of mineralization in the Japanese deposits as explained by Iwao (1953). However, the segregation process of diaspore-pyrophyllite-kaolinite-alunite-silica was achieved through the alteration of lavas and pyroclastic rocks at shallow depth by ascending acid solutions of volcanic and subvolcanic derivation. During ascent the temperature decreased from 600° to 150°C and the solution became progressively more acidic, selectively mobilizing the alkalis which hydrated and laterally giving rise to zones enriched in sericite and montmorillonite. Simultaneously the residue (mainly alumina and silica) reacted with the components of the solution.

Recoverable reserves of all grades of pyrophyllite total approximately 10 Mt, with an estimated additional 20 Mt in place.

Canada: The only current commercial source of pyrophyllite in Canada is on the Avalon Peninsula of Newfoundland, near the small town of Toxtap. Pyrophyllite was first extracted in the area in 1904 when a shipment of 1750 tons was sent to the US. Thereafter production continued intermittently, the most consistent period being 1938-1948 when Industrial Minerals Co. of Newfoundland mined and milled 6500 tons. However, Newfoundland Minerals Ltd., a wholly owned subsidiary of American Olean Tile Co. Inc. of the US, acquired the operation in 1956. Since then production has been continuous.

The pyrophyllite occurs in a narrow belt running south of Conception Bay in eastern Newfoundland and along the east side of the Precambrian Holyrood granite batholith. It is thought that hydrothermal solutions, moving up via faults and shear zones from the granite, may have recrystallized rhyolitic rocks into the fine-grained assemblage of quartz, sericite, and pyrophyllite. Rhyolitic rocks remote from the granite showed no signs of pyrophyllite mineralization.

A future Canadian source of pyrophyllite may well be the Senneterre deposit located in Carpentier Township, Abitibi region, Quebec, which has been actively prospected since the 1930s. It was not until 1962, however, that a mapping project conducted by the Quebec Dept. of Natural Resources identified the rock in the shear zone as pyrophyllite. Domtar Ltd. optioned the property between 1964 and 1974. Since then it has been in the hands of Descarreaux & Mousseau Tremblay Inc. of Quebec. The property, which is within the mineral-rich Precambrian Shield area of Canada, has pyrophyllite mineralization in a series of zones associated with sheared metamorphic volcanics and pyroclastics ranging in composition from andesites to rhyolites. Again, a metasomatic origin has been assigned to the deposit.

Some occurrences of pyrophyllite have been reported in western Canada. For example, the northeastern portion of Kyquut Sound, a small inlet on the west coast of northern Vancouver Island, has been described as a pyrophyllite area. In addition, Mountain Minerals Ltd. of Lethbridge, Alberta, has been actively investigating several pyrophyllite claims in western Canada.

Brazil: The Onca de Pitangui and Pitangui deposits in the state of Minas Gerais and the Santano de Parnaíba deposit in the state of São Paulo contain more than 1 Mt measured reserves of pyrophyllite. Brazil's vast refractory producer, Magnesita SA, has an output of about 60 kt/a at Belo Horizonte. The entire production is consumed by the company, largely for the manufacture of ladle linings. Finapa Assessoria Commercial Industrial Ltda. of São Paulo claims to have a 100 kt/a capacity pyrophyllite mine which supplies the ceramics industry. Cia. Minerá Agregados Calcáreos SA of Lima, Peru, has been mining and processing a mineral

similar in chemical composition and uses to pyrophyllite, although it is mineralogically different. The company has also isolated a large deposit of pyrophyllite—the only one on the Pacific coast of South America.

Minor Producing Countries

India: Three deposits at Madhya, Aradesh, Rajasthan, and Uttar Pradesh produce a total of approximately 15 kt of pyrophyllite annually.

Argentina: Argentinian pyrophyllite is mined principally from the Juanita del Puerto mine in La Rioja province and is used in the manufacture of electrical porcelain and vitreous enamel. It produces less than 10 kt/a.

South Africa: Pyrophyllite, locally referred to as *wonderstone*, is mined near Ottosdal in the Lichtenburg district. The deposit is of the hydrothermal type and crops out in a series of elongate lenses associated with two lineaments which transgress rhyolite and acid types of the Dominion Reef series of the Witwatersrand System. The material mined in fact is a metasedimentary rock made up of pyrophyllite (89%), chloritoid, epidote, and rutile. The product, with an average chemical composition of 55.5% SiO_2 , 35.24% Al_2O_3 , 0.31% MgO , 2.8% TiO_2 , and 6.15% loss on ignition, is different from a standard pyrophyllite in having a Mohs' hardness of 8. Naturally, the end uses are therefore different, the main ones being bushes for submerged pumps, inserts for sluiceway nozzles, spigots for coal washing plants, and abrasion- and acid-resistant linings for pipes and coal chutes.

Swaziland has been producing small tonnages of pyrophyllite for some years now, particularly from the Usetu area between the Mkhondvo and Great Usutu Rivers. However, production is only on the order of a few hundred tons a year.

Thailand: Minor production of pyrophyllite occurs in central Thailand for general ceramic uses in Southeast Asia. The mining capacity of the Thailand operation is on the order of 12 kt/a. Mineralogically the Thailand material is a mixture of pyrophyllite, kaolinite, and diasporite according to X-ray diffraction analysis.

Turkey: Turkey has been a commercial producer of pyrophyllite since 1976 when Endustrie Mineralleri ve Taslari Sanayi (Industrial Minerals of Turkey Ltd.) started up its production in the Malatya Province of eastern Turkey. Approximately 6 Mt of pyrophyllite are contained in hydrothermally altered dacite tuffs found in lenses scattered over a wide area. Three main grades are mined: a green colored massive block variety; a white soft clay material; and a sericite-contaminated dark green pyrophyllite.

Current production is around 3 kt/a. The entire production is currently being consumed by Canakkale Ceramic Refractories, part owners of Industrial Minerals of Turkey, in its production of wall tiles and cordierite products, and as a natural grog for kiln furniture such as setters, slabs, pins, and posts. There are plans to produce pyrophyllite for the production of pyrophyllite/zircon ladle lining bricks. Later the market for pyrophyllite as a paper filler will be examined.

EXPLORATION

Exploration programs for pyrophyllite are usually conducted in areas where geological evidence indicates that underlying rocks belong to acid-volcanic complexes. Pyrophyllite is found in hydrothermal alteration zones associated with faults or shears which transect these felsic igneous rocks.

Field Techniques

Aerial photographs are most useful in reducing the area to be explored to a manageable size. This is achieved by plotting on the photographs linear features which may represent faults or shear zones. The geologist then examines each of these lineaments on the ground and undertakes reconnaissance work along favorable zones.

Pyrophyllite is generally identified in the field by its translucent green color and waxy feel. In addition, outcrops of chalcedonic pyrophyllite tend to be bolder than the enclosing rocks and display a characteristic weathering pattern, whereas outcrops of chloritic pyrophyllite are typically subdued and feature jagged boulders.

When a discovery has been made, drilling or trenching is performed to provide fresh samples for preliminary laboratory evaluation.

Geochemical

The pattern of alteration in pyrophyllite deposits is usually zoned, with a central core of chloritic pyrophyllite surrounded by imperfectly segregated zones of chalcedonic pyrophyllite and sericitic pyrophyllite which grade into unaltered host rocks. Geochemical techniques have been found to be successful in delineating the zonal pattern and defining the margins of the ore body.

Surface samples could be collected on a 10-m² grid basis. In areas of good outcrop conditions, clean representative samples can be obtained without difficulty. However, in areas of poor outcrop conditions shallow drilling or trenching may be necessary.

Contoured plots of alumina and total-alkali values are prepared and superimposed on a geological plan. The results not only define the zonal pattern but also provide a good basis for designing detailed drilling programs. As an example, in the evaluation of the Pambula deposit 3000 samples, both surface and subsurface, were analyzed for potash alkalis and alumina values. These were used to prepare histogram plots and cumulative frequency distribution curves. These plots confirmed the bimodal distribution of both Al_2O_3 and K_2O populations, probably representing both a primary and a secondary alteration phase and two periods of mineralization. The primary mode has a definite positive skew with the greater proportion of the mineralization showing alkali values at less than 0.5% K_2O . The mean values of K_2O and Al_2O_3 suggest a composition for the pyrophyllite mineralization occurring during the primary alteration phase of 12.7% Al_2O_3 and 0.57% K_2O .

Drilling

Two kinds of drilling operations generally apply to pyrophyllite exploitation, diamond drilling and percussion drilling.

Diamond drilling provides core samples to enable the geologist to predict the subsurface behavior of the ore body and to find and correlate the zonal pattern determined from surface observations. Diamond drill holes are usually inclined at low angles and designed to penetrate the entire width of the steep dipping ore bodies.

Percussion drilling is carried out as a fore-runner to production operations for detailed grade evaluation. Vertical holes are usually drilled on a square grid spacing of between 1 and 3 m and chip samples are collected at 1- or 2-m intervals to depths of up to 10 m. Compressed air raises drill chips to the surface and into a cyclone where they are removed from the airstream and discharged into a sample collecting tube.

EVALUATION OF DEPOSITS

Specifications

A variety of grades is available from each deposit. Grade classification takes account of market requirements on the one hand and mineralogy of the ore on the other. Ore is graded according to its pyrophyllite mineral content and the nature of abundance of other minerals in the ore. Mineralogy is determined indirectly by chemical analysis, principally for Al_2O_3 , K_2O , and Fe_2O_3 contents.

Evaluation

Grades and reserves are calculated by conventional geological techniques and the results used to optimize quarry design.

22. Quartz/Silica Sand

MARK J. ZDUNCZYK

INTRODUCTION

Commodity Description

Industrial grade silica is usually sand and is essentially pure quartz (SiO_2).

Location

Deposits of industrial silica sand are relatively common and occur in many geographic regions. In the United States, these deposits are mined in the following states: Arkansas, Alabama, California, Colorado, Connecticut, Florida, Georgia, Idaho, Illinois, Indiana, Louisiana, Michigan, Massachusetts, Minnesota, Missouri, Nevada, New Jersey, New York, North Carolina, South Dakota, Tennessee, Texas, Virginia, Washington, West Virginia, and Wisconsin.

Products

The main silica products are glass and foundry sand. Other products include filtration sand, blast sand, proppant sand, traction (engine) sand, as well as other specialty sand products. The chemical and physical characteristics of the two main products follow.

For glass or melting sand, the SiO_2 content of the processed product must exceed 99.5%, the Al_2O_3 should consistently be less than 0.30%, and the Fe_2O_3 should not exceed 0.030% by weight. Limitations are also placed on TiO_2 , Cr_2O_3 , CaO , MgO , ZnO , Na_2O , and K_2O , the amount depending on the glass product which is manufactured. For example, the bottle (glass container) industry can tolerate varying amounts of minor oxides, but float glass (plate glass) requires a more consistent oxide content. To some degree, glass manufacturers can adjust their processing to accommodate sand that does not meet rigorous specifications.

Grain size for glass sand should have less than 1% retained on the 550 μm (30 mesh) sieve and have 8 to 10% retained on the 375 μm (40 mesh) sieve. No more than 5% should pass the 140 mesh sieve.

Heavy minerals, such as ilmenite and leucoxene, are limited by weight and number of particles. These limitations are placed on the material retained on the 550-375 μm (30 to 40 mesh) sieves. Generally, the glass manufacturer provides these specifications.

For foundry sand the SiO_2 content must exceed 98%, but less emphasis is placed on the other oxides except the base oxides, such as CaO and MgO . The greater amount of base oxides a sand contains, the more synthetic binder is necessary to make the mold or cast. The amount of synthetic binder is called acid demand.

Grain size for foundry sand varies depending on the products a foundry makes. Generally, the coarse grain sand is used for large iron and steel castings while a finer grain sand is used for smaller brass, aluminum, and other alloy castings. Grain shape also plays a role in the need for chemical binders. Round grains free of base oxides will have less surface area than angular grains and, therefore, use less binder. Heavy minerals generally have little effect on foundry sands.

Types of Occurrence

Industrial silica is mined from sedimentary sandstones, both loosely and well cemented, metamorphic quartzites and

orthoquartzites, igneous pegmatites, and unconsolidated sand deposits derived from the aforementioned rock types. Some quartz-rich kaolin clay deposits and quartzofeldspathic deposits may occasionally be of economic interest.

MINING METHODS

Silica sand producers surface mine by various methods. Some operators mine unconsolidated sand by means of a front-end loader, diesel shovel, or equivalent. The sand is loaded into trucks which transport the material to a nearby hopper that feeds the processing plant. When the water table is high, dredging may be used. Dredging removes sand below the water table usually with a 20- to 30-cm (8- to 12-in.) suction pipe. Sometimes "cutterheads" are used in conjunction with the suction pipe and break the material free from the bank. The sand is then transported from the dredge in slurry through a pipeline to a stockpile. Hydraulic mining may be used in unconsolidated and loosely consolidated sand. In this method, water is jetted under high pressure against a bank, washing the sand into a sump where the sand is transported through a pipeline to a stockpile and later processed. A dragline clamshell is often used in unconsolidated sediments above and below the water table and in some instances an hydraulic excavator may be used in shallow deposits.

In rock, such as quartzite, well-cemented sandstone, or pegmatite, drill and blast techniques are used. The fragmented rock is mined by shovel or front-end loader and loaded into trucks which haul to a nearby hopper that feeds a crusher. After crushing, it is conveyed to the processing plant. Underground operations are limited to a few cases where the deposit is consolidated and the overburden is too thick to strip economically. The room-and-pillar method of mining is used in these cases.

EXPLORATION

The different geologic occurrences of silica sand lend to different types of exploration techniques. However, a literature search is usually the first step in exploration. Along with this search, defining the market area is very important, with the market a major factor determining whether a site is explored. Most state geological surveys are well aware of their state's silica sand deposits and can be very helpful in providing information. Government agencies are generally less helpful unless a significant study was undertaken in that area. Nevertheless, most of the silica sand deposits in the United States are known and some have been investigated several times. Once a site is selected, the geologist must perform a site reconnaissance and subsequent geologic mapping to determine the number of drill holes and/or test pits locations and patterns.

In unconsolidated deposits such as those similar to New Jersey or South Carolina where the water table is high, using a rotary drill rig with a 7.6-cm (3-in.) OD split spoon sampler is recommended. A split spoon sampler is a pipe which is split down the middle where it can be opened to observe and collect the sample. The spoon is driven into the deposit by a 136-kg (300-lb) weight. A "drag bit" is used to deepen the hole to the desired depth where the next sample is to be taken. Bentonite mud is usually employed during drilling to

case the hole and prevent collapse. Mud drilling rigs should be equipped with a large mud pump [10×12.7 cm (4×5 in.)] 136-kg (300-lb) weight to drive the sampler and an experienced mud driller. Failure to have these essential components may result in poor recovery of samples, untimely delays, and wasted efforts. During this type of drilling, continuous sampling is very important. After logging the samples, they are examined petrographically and splits are sent to analytical laboratories for determination of the critical oxides.

In loosely consolidated or consolidated sandstone, quartzites or pegmatites core drilling is usually required. A drill rig, equipped with NX size wire line (54.9-mm) coring capabilities is generally used. When the rock is loosely cemented, bentonite mud may be used to help in recovery of a full sample. The core is logged by a geologist who is particularly interested in both type and amount of cementation in addition to the degree of iron staining on the quartz grains.

Two types of auger drilling can be used in unconsolidated deposits. Hollow stem augers with 7.6-cm (3-in.) OD split spoon sampler is limited to depth and water table. A split spoon sampler is periodically lowered through the hole in the augers. Solid stem augers have been used, but the samples

which flow up the sides of the augers are mixed and not usually representative. This type of drilling is inexpensive, but it is not a recommended method to explore a deposit.

Water jet drilling can drill quickly, but produces a mixed sample that may be difficult to interpret. Test pitting with backhoe or excavator shovel can be useful in shallow deposits. Geophysical techniques, such as seismic or resistivity, are not very useful when quality of the material must be tested.

Percussion air drill rigs, such as those used to drill holes for blasting rock, can be used for quickly determining depth. However, the samples are mixed from various horizons and, therefore, difficult to use to delineate quality.

Rugged, swampy, or mountainous terrain is often encountered in exploration drilling. All terrain drill rigs are available; however, proper drilling and sampling equipment should be placed on the rig.

The number and location of drill holes generally rely on economics. Most geologists and producers would prefer to delineate the deposit as accurately as possible because the final silica product must meet stringent specifications. Therefore, tight delineation of the variations within the deposit is desirable. The geologist, with the information available from drill holes, literature, mapping, and geologic intuition, must decide whether the deposit is worth exploiting.

23. Sand and Gravel

HAROLD B. GOLDMAN

In commercial usage "sand" applies to rock or mineral fragments ranging in size from three-thousandths of an inch to a quarter of an inch. "Gravel" consists of rock or mineral fragments larger than 6 mm ($\frac{1}{4}$ in.) ranging up to 89 mm ($3\frac{1}{2}$ in.) maximum size.

The construction industry consumes 90% of the sand and gravel produced; the remainder is sand used for specialized products such as glass.

UTILIZATION

The building industry uses sand and gravel chiefly as aggregate in portland cement concrete, mortar, and plaster; the paving industry uses sand and gravel in both asphaltic mixtures and portland cement concrete. Aggregate is commonly designated as the inert fragmental material which is bound into a conglomerate mass by a cementing material such as portland cement, asphalt, or gypsum plaster.

Portland cement concrete consists of sand and gravel surrounded and held together by hardened portland cement paste. Concrete mixes commonly contain 15 to 20% water, 7 to 14% cement, and 66 to 78% aggregate. Sand and gravel used as concrete aggregate have to meet many requirements (Goldman and Reining, 1983). Premature deterioration of concrete has been traced in many instances to the use of unsuitable aggregates.

Asphaltic mixtures used predominantly for paving consist of combinations of sand, gravel, and mineral filler [material finer than 0.07 mm (0.003 in.)], uniformly coated and mixed with asphalt produced in the refining of petroleum. Except for the addition of mineral filler, sand and gravel used as asphaltic aggregate must meet the same general physical requirements as materials used for portland cement concrete aggregate.

General Requirements of Aggregates

Construction aggregate has many requirements that are difficult to meet if only unprocessed material from natural deposits is used. Suitable material is composed of clean, uncoated, properly shaped particles which are sound and durable. Soundness and durability are terms used to denote the ability of aggregates to retain a uniform physical and chemical state over a long period of time so as not to cause disruption of the concrete when exposed to weathering and other destructive processes. To have these attributes, individual particles must be tough and firm, possessing the strength to resist stresses and chemical and physical changes, which may cause swelling, cracking, softening, and leaching. The aggregate should not be contaminated by much clayey material, silt, mica, organic matter, chemical salts, and surface coatings.

The quality of aggregate depends upon its physical and chemical properties. These, in turn, may be inherent mineralogical and textural features of the rock or may be the effects of later changes such as tectonic fracturing, mechanical or chemical weathering, or incrustations.

The physical properties most significant with regard to concrete are: (1) abundance and nature of fractures and pores, (2) particle shape and surface texture, and (3) presence of material which may cause volume change. An aggregate is considered to be physically sound if it is adequately

strong and capable of resisting the agencies of weathering without disruption or decomposition. Minerals or rock particles that are physically weak, extremely absorptive, and easily cleavable are susceptible to breakdown by weathering. The use of such materials in concrete reduces strength or leads to early deterioration by promoting weak bond between cement and aggregate, or by inducing cracking, spalling, or popouts. Severely weathered, soft, micaceous, or porous materials may cause localized stresses to develop in concrete by swelling and shrinking during wetting and drying or freezing and thawing cycles.

Suitability of the Various Rock Types: Sedimentary rocks show a wide range in physical qualities and suitability. Sandstones and limestones, if hard and dense, are ordinarily satisfactory, but many sandstones are friable and excessively porous and commonly are clay-bearing. Shales generally make poor aggregate material, being soft, light, weak, and absorptive. Most igneous rocks are satisfactory, being normally hard, tough, and dense. Tuffs and certain flow rocks may be extremely porous and have high absorption and low strength. Metamorphic rocks differ in character. Most marbles and quartzites are usually massive, tough, and dense. Gneisses are ordinarily very tough and durable. Some schists contain micaceous minerals which are undesirable because they are soft, laminated, and absorptive. Micaceous minerals are susceptible to weathering along cleavage planes and thereby impair strength and durability. Some schists and slates in particular are thinly laminated and tend to assume flat slabby shapes which lack strength.

Any or all of these rock types may be rendered undesirable because of harmful exterior coatings. Weathering processes, particularly the action of ground waters, deposit these coatings. The most common coatings are calcium carbonate, clay, silt, opal, chalcedony, iron oxide, manganese oxide, and gypsum. Particles with these coatings are generally undesirable as aggregates. The bond between particle and coating may be weak and decrease the strength of the aggregate-cement bond.

Chemical Properties: The chemical properties which may affect service life of concrete are (1) reaction of certain rocks and minerals with high-alkali cement (alkali-aggregate reactivity); (2) leaching of water soluble substances; (3) solution of certain secondary minerals, such as the zeolites, to release sodium and potassium which aids in attacking susceptible aggregate particles; and (4) oxidation by weathering to produce compounds that may retard cement hydration.

Alkali-aggregate reactivity has been discussed at length in many publications. A reactive aggregate is any rock, gravel, or sand that contains one or more constituents that react chemically with the alkalis (sodium and potassium) in some types of portland cement. This reaction causes expansion, cracking, and deterioration of concrete and arises from osmotic pressures produced by the formation and hydration of alkali-silica gels. The gels are formed through interaction between reactive silica in the mineral aggregate and the alkalis which are liberated by the cement during hydration. Opal (amorphous hydrous silica) is the most conspicuous aggregate material reacting in this manner. Other rocks and minerals known to be reactive are: glassy volcanic rocks of medium to high silica content (andesite and

rhyolite), chalcedonic rocks, certain phyllites which contain a hydromica, and the minerals tridymite and heulandite. Any rock containing a significant proportion of reactive substances may be deleteriously reactive; thus normally non-reactive sandstone, shale, basalt, granite, and other rock types may be harmful if impregnated or coated with opal, chalcedony, or other reactive substance.

Certain sulfide minerals, such as the iron sulfides, pyrite, and marcasite, oxidize and cause unsightly rust stains or generate acidic compounds injurious to the concrete matrix and cause popouts. Chemical salts such as sulfates, chlorides, carbonates, and phosphates also occur in some aggregates. Some of these substances dissolve easily or react to impede the setting of the cement.

A chemical alteration contributing to physical unsoundness is hydration. Shales, clays, and some rock nodules are examples of materials which expand when they absorb water and shrink as they dry. This absorptive character increases the rock's susceptibility to disruption by weathering.

Most of the foregoing features can be observed in the field, and on the basis of these observations, laboratory test procedures can be set up to further evaluate the properties of the aggregate.

GEOLOGIC OCCURRENCE

In the United States, sand and gravel is obtained commercially from rock units of many types and ages in open pit operations. The principal sources are along existing or ancient river channels and in glaciated areas; marine and lake deposits and older geologic formations are significant but of lesser importance.

Classification of Deposits

Stream Deposits.

Stream Channel Deposits—Stream channel deposits consist of sand and gravel deposited in stream beds along present or former stream courses. Most channel deposits are generally easily accessible and easily mined.

Materials in these deposits are desirable as aggregate for many reasons. The natural abrasive action of stream transport has removed most of the soft weak rocks, leaving only the harder and firmer particles. These latter particles have undergone some degree of rounding and are subrounded to well-rounded, a desirable aspect for use in concrete.

Most channel sand and gravel deposits are replenished by material carried by seasonal floods, except in portions of the streams downstream from dams. Overburden is rarely present, but high flood waters may leave silt, clay, and wood debris covering parts of some channel deposits. The size of gravel gradually decreases downstream in the streams with long reaches. Commercial production is concentrated in the deposits where a proper blend of sand and gravel can be obtained. Fortunately, the favorable portions of many streams occur in flat-lying areas near population centers.

Channel deposits normally are free of excessive amounts of silt and clay and most deposits contain sand and gravel in the size gradations necessary for concrete design. Mining operations are often relatively simple, consisting of no more than washing and screening to obtain suitable aggregate. In spite of these qualities some deposits are unsuitable because they contain harmful ingredients such as physically unsound or chemically reactive rocks. The nature of the material in the stream channel is determined in large part by the nature of the source rocks within its drainage area. Different geological formations in a drainage basin contribute a variety of rock types which show a wide range in chemical composition and degree of weathering.

Flood Plain Deposits—True flood plain deposits consist of material deposited on plains bordering streams by periodic overflow of the streams from their channels. The sediments deposited are normally composed of silt and sand grains. However, fine materials may mantle usable deposits of sand and gravel, particularly in areas where, in the geologic past, the streams were more vigorous and transported greater volumes of coarser material. The sand and gravel in these older, deeper flood plain deposits is similar to that in channel deposits and is suitable for use after overlying flood plain silt layers are removed.

Terrace Deposits—Stream terrace deposits are benchlike deposits of sand and gravel which border a stream but lie above the level of the present flood plain. These deposits are remnants of older flood plains through which the stream has cut. Terrace deposits, because they are above the stream level, may be more desirable than stream channel deposits if water tables are shallow and abundant ground water makes stream channel and flood plain operations difficult. However, there is little possibility of replenishment of terrace deposits. The materials in these deposits have the general properties of stream channel materials, but weathering processes may have diminished the quality of some of their constituents by converting certain minerals to clay. Not all terrace deposits can be used for aggregate. Some deposits are only thin veneers of sand and gravel deposited on a stream-cut bedrock surface. The materials in the deposit may not be suitable if they have undergone post-depositional weathering or if the grains have become coated with harmful substances due to the action of ground waters.

Alluvial Fans: An alluvial fan is formed when streams carrying large volumes of sand and gravel down a steep mountain slope enter an adjacent valley or plain. The abrupt change in slope causes a decrease in the speed of the stream. This change causes the stream to deposit the sand and gravel it has been carrying. The deposited matter spreads in a gently sloping fan-shaped mass from the mouth of the canyon onto the valley floor. The heavier, coarser material is deposited near the mouth of the valley, while the finer material is carried out toward the edges of the fan. Alluvial fan deposits have been found to reach depths up to and occasionally more than about 61 m (200 ft).

Fan deposits, because of the frequent shifting of the stream channel, ordinarily contain lenticular beds or tongues of poorly sorted sand and gravel interbedded with varying proportions of silt and clay. The particles are subangular to angular in the fans built by streams with small drainage areas. The particles in large fans, covering several square kilometers (miles), are generally subangular to subrounded. Suitable aggregate is obtained from alluvial fans which are free from thick clay lenses.

In the past, the deposits were replenished during periods of flooding until the time that flood control dams were built to control the rivers.

Glacial and Fluvial-Glacial Deposits: Sand and gravel is produced commercially from open pit operations in glacial deposits in the midwestern and northeastern parts of the United States. The bulk of the sand and gravel was deposited directly or indirectly from continental ice sheets which originated in Canada and spread south into the United States. Glacial deposits that have been subjected to stream action are called fluvial-glacial deposits.

The glaciation period consisted of advances and recessions of the continental ice sheets which were several thousand feet thick, and moved roughly north to south.

Fragments of the rocks in the areas over which the glaciers passed, such as the igneous rocks in Canada, were

picked up and incorporated in the glacier. When the glacial ice melted, the debris of clay, silt, sand, and pebbles and boulders were deposited as glacial till. When the advance and melting of the ice were in the balance, the debris deposited along the margin of the glacier formed irregular ridges termed moraines. As the water flowed away from the melting glaciers, the glacial debris was transported and deposited in outwash plains or elongate valley trains which are now major sources of sand and gravel (Ekblaw and Lamar, 1964). In addition, kames (hills) and eskers (ridges) of sand and gravel were deposited by melt waters within the ice sheet.

The fluvial-glacial deposits exhibit a better degree of sorting and contain less clay than the true glacial deposits and are of high enough quality to yield satisfactory aggregate comparable to true stream sand and gravel. Generally, the fluvial-glacial deposits are thinner than stream deposits in regions of considerable topographic relief.

Outwash Deposits—Outwash debris varies in size with the distance from the former glacial ice. The coarsest materials, pebbles, cobbles, and boulders, were deposited near the glacier, and the finer materials, sand, silt, and clay, were carried successively farther away from it. Since the water velocities fluctuated, the maximum size of transported particle varied and the deposits are characterized by great variation in particle sizes. Instances are cited where layers of gravel abruptly terminate, to be replaced by thick accumulations of silt or clay.

Kames and Eskers—Kames are hills composed of material deposited by glacial melt water in vertical crevasses or holes in the glacier, generally at or near its front. Eskers consist of material deposited in the beds of streams that flowed under or in the glacier. When the ice melted, the kames remained as rounded hills, and the eskers were left as ridges. The materials in these deposits, which show a wide variation in size and physical characteristics, are a common source of sand and gravel.

Beach and Dune Deposits—During the last stage of glaciation, the Lake Michigan basin was occupied by a larger lake whose level varied with the advances and recessions of the glacier. Each stage is marked by beach ridges of gravelly sand. In places, the beach sand has been blown into dunes. These deposits are suitable as sources of sand, although urbanization and preservation as natural and recreational areas have removed many of them from consideration as minable reserves.

Moraines—True glacial deposits such as moraines have been transported solely by glacial ice with little or no reworking by streams. Moraine debris contains material of diverse size, shape, and quality ranging from pulverized rock flour to erratic boulders and generally is usable only after expensive processing.

Dredge Tailings: As a result of bucket dredge operations for gold, huge furrowlike ridges of gravels have been accumulated as tailings along many of the western state streams. A normal gold-dredging operation involves washing and screening the stream deposit. The oversize gravel, which ordinarily consists of everything over 13 or 19 mm ($\frac{1}{2}$ or $\frac{3}{8}$ in.), is washed and sent to tailings piles behind or alongside the dredge. The undersize fine gravel and sand are then processed to remove the gold and returned to the dredge pond and subsequently covered by other oversize tailings. This results in segregated deposits of fine gravel and sand which underlie coarser gravels, requiring that considerable material be processed by aggregate producers to obtain the desired gradings of sand and gravel. Most commercial operations employ equipment to crush the oversize tailings. Tailings piles which have not been subjected to excessive

weathering contain material as suitable as the related stream deposit.

Older Geologic Formations: Pre-Quaternary formations, particularly partly consolidated sedimentary beds of sandstone and conglomerate, afford usable sources of aggregate when post-depositional weathering has not been too complete. Ordinarily, these formations have been subjected to long periods of weathering and are either too well cemented or contain too much clayey material to be processed economically. Accessibility of the deposit and depth of overburden also present problems.

The pre-Quaternary formations which are composed of well-indurated sedimentary rocks or hard crystalline rocks require expensive quarrying operations to obtain suitable material for aggregate.

Beach Deposits: Sand and gravel formed by the winnowing action of currents and waves on a beach make excellent aggregate. The gravel and coarse sand size particles are generally well-rounded, hard, and firm. The sands are commonly composed predominantly of resistant quartz and feldspar. Most beach deposits, however, are thin and lack proper size gradation.

Distribution of Deposits

The occurrence of sand and gravel in the United States is related to geologic processes. On a geographic-geologic basis, in the northern states, the principal sand and gravel resources are various types of glacial and outwash glacial deposits. Marine terraces, ancient and recent geologically, are the major sand and gravel sources in the Atlantic and Gulf Coastal Plains. River deposits are the prime sources in several of the southeastern and south-central states. In the Great Plains, sand and gravel are mainly stream deposits. On the West Coast, deposits are principally alluvial fans, stream deposits, beach and dune sand, and fluvial-glacial deposits.

Offshore deposits, although of minor importance tonnage-wise, are mined along the east coast from Washington to Boston and in the Great Lakes.

EXPLORATION

Exploration for sand and gravel is generally guided by the needs of the potential producer. There are certain criteria that a deposit should meet in order to be of economic interest for a commercial producer, such as proximity to market, ease of obtaining the necessary mining permit, and a deposit of sufficient quantity to amortize the cost of a modern processing plant.

As sand and gravel is a low-cost, high-volume commodity, it cannot be transported far before the cost of transportation equals or exceeds the cost of the processed material at the plant. Thus, in most urbanizing areas the proximity to market would determine the target area for exploration. In aggregate-deficient parts of the country where materials are transported hundreds of miles, the target area naturally would be much larger.

Another important criteria to be met before field exploration begins is the socioeconomic restrictions on a potential mining operation. If the governing bodies have adopted a policy of refusing to grant operating permits, there would be no purpose for exploring in that jurisdiction. Also, there should be an awareness of the opposition that would be generated by conservation and ecology minded groups to granting of mining permits.

The size of the deposit is critical. In some parts of the country, where large volumes of sand and gravel are consumed, new sand and gravel plants cost millions of dollars.

In order to amortize the cost of such a plant, the deposit should contain sufficient reserves for at least 20 years.

Naturally, in prospecting for sand and gravel for non-commercial production, such as for use in dams, the foregoing criteria rarely apply. In this instance, the quantity and quality are the prime factors to consider.

Field Technique

Preliminary field evaluation by a geologist or by an engineer with some geologic training may often suffice to evaluate a deposit as a possible source of aggregate material. The characteristics that bear upon the usefulness of a deposit as a source of aggregate material have been determined by the geologic processes by which the deposit was formed and subsequently modified. A basic understanding of the processes, therefore, is helpful to the person evaluating it. The important characteristics are types and physical condition of the rock, grading, rounding and degree of uniformity, particle size and shape, location, thickness and type of overburden, and ground water level.

By the judicious use of geologic maps, a geologist can determine the type of materials to be encountered in a certain drainage area and predict the type of alluvial material to be found in a given stream channel. He thereby can recognize likely sources of aggregate and often can rule out areas unlikely to contain suitable materials. The geologist uses commercial sand and gravel deposits as a yardstick to guide him in evaluating new deposits. By comparing service records and laboratory test results with the petrographic character of commercially proven aggregates, the geologist builds up a background of data from which he can extrapolate to predict the behavior of untested deposits of similar petrographic character. This technique has been used successfully by the US Bureau of Reclamation in preliminary planning studies for large structures that require large amounts of suitable aggregates. In many instances field evaluation has obviated the need of expensive and time-consuming laboratory tests.

Target Areas—As outlined in the section on geology, those areas to be prospected for sand and gravel are predominantly those associated with either the present stream drainage or ancient drainages. Clues to buried or older deposits may be gleaned from well drilling logs, geophysical data, and from geologic reports.

Aerial photographs, coupled with topographic maps, are essential tools. Any geologic information in the form of maps or reports should be researched. In most instances, the state geological surveys can provide the necessary maps.

The initial exploration can be greatly expedited with the use of airplanes, preferably a helicopter, to observe promising geologic features. Preliminary investigations, which include determining such features as crude estimates of volume of available material, thickness and type of overburden, and water and power availability and access, are based primarily upon visual examination, either by a geologist or someone with experience in aggregate production.

Detailed Exploration: The method of exploration will depend upon the particular set of conditions; the objective being to obtain representative samples of the entire deposit and to delineate the dimensions of the deposit.

No matter what method of exploration, ultimately representative samples must be obtained so that standard laboratory acceptance tests can be performed on the samples.

Where the deposit is shallower than 9 m (30 ft), test pits may be excavated with bulldozers, backhoes, clamshells, or dragline. The location of the water table often will determine the type of test pit.

For deeper deposits, truck-mounted drill rigs should be used. Ordinarily, truck-mounted bucket augers, which use buckets from 46 to 91 cm (18 to 36 in.) in diameter, perform satisfactorily when large boulders are not present in the deposit. When drilling beneath the water table, steel casing is used to prevent the hole from caving.

Other drilling rigs, such as clamshells and reverse circulation drills, perform satisfactorily. Choice of drilling method will depend upon the availability of competent drillers in the area.

Geophysical methods can be used in conjunction with a drilling program. Geophysics may be used to check continuity of geologic units between drill sites or beyond a known deposit. For example, electrical resistivity techniques may be used to locate thick zones of clay interbedded in the sand and gravel. The depth of a sand and gravel deposit resting on a hard bedrock surface can be determined by means of refraction seismic methods.

The cost of geophysical methods equals the cost of drilling, on an hourly basis. However, much more information is obtained within the same time interval through geophysics.

Obviously, geophysical methods are useful exploration tools but cannot substitute for the other methods when samples must be obtained for laboratory testing. Standard laboratory acceptance tests are used to determine the suitability of the deposit. Equally important as laboratory testing is the sampling in the field. Where possible, large bulk samples should be obtained and quartered in the field. If it is possible, enough material should be stockpiled and trucked or railed to an existing plant to determine size gradation and quality of the finished product.

As an integral part of the exploration program, cross sections should be drawn of the deposit and estimates made of the quantity of material available. This figure should be reduced by the percentage of waste material, such as beds or lenses of clay and silt, and the loss of material to setbacks and finished slopes required by mining permits.

General Specifications

The study of the results of laboratory tests of aggregates that have good service records in concrete has led to the establishment of certain minimum requirements of specifications to which aggregates are expected to conform. These specifications are designed so that completely serviceable concrete may be made, using any aggregate that meets the requirements. Most specifications are written by government agencies, engineering societies, and concrete technologists and attempt to conform to one standard set of specifications, those set up by the American Society for Testing and Materials. Modifications of these standards for certain types of concrete work make it difficult to compare individual requirements of the various organizations. Therefore, to evaluate the suitability of a deposit by judging the test results of selected samples is a difficult task. Some deposits which may not meet certain required specifications may have to be utilized because of other outside factors, such as the greater expense of hauling a more suitable aggregate.

In general, aggregate from an untried deposit will be satisfactory for most uses if it meets the minimum standards of the US Army Corps of Engineers, and the US Bureau of Reclamation.

24. Talc

RICHARD H. OLSON

COMMODITY DESCRIPTION

Talc is a mineral with fixed chemical composition. In industry, however, the name is applied to a number of mixtures of talc and talclike minerals, e.g., anthophyllite, antigorite, chlorite, dolomite, magnesite, mica, pyrophyllite, serpentine, and tremolite. The term "talc," therefore, to a mineralogist has a distinctly different connotation than to a miner or ore-purchaser. The remainder of this article is largely directed toward the latter two groups.

The term "steatite," originally a mineralogist's term applied to pure talc, in today's industrial usage generally refers to a massive variety of talc suitable for machining into electrical insulators.

The term "soapstone" is a rock name, not a mineral name. It refers to a massive coherent rock which is generally composed predominantly of impure talc containing relatively minor amounts of chlorite, mica, and various amphibole and pyroxene minerals. Its marked tendency to retain block form when broken out of its outcrop resulted in its abundant use by prehistoric Indians for the manufacture of utensils and ornaments.

As with most other ores, local terminologies have been developed for talc ores and related rocks by both the miners and producers. Examples of this plus a discussion of technological terms applied to talc products are given in Chidester, Engel, and Wright (1964, pp. 8-10).

Bodies of more or less pure talc are referred to as "talc schist." In the mining of talc ores it is not uncommon to have in near proximity separate and distinct bodies of pure talc schist and tremolitic ores. Therefore, tremolite can be a coproduct of talc mining or talc can be a coproduct of the mining of tremolitic talc ores.

Recent federal government investigations into health and safety matters have resulted in tremolite being likened to asbestos. A summary of the results of one of the early government-sponsored symposia on this subject was compiled by Goodwin (1974). Such investigations have led many consumers to switch away from tremolite-containing products over the past decade or so. No such firm stands have yet been taken on this matter re tremolite, as is the case with asbestos, and this reluctance to decide one way or the other continues to complicate the lives of those who manufacture products from tremolitic ores.

MINING METHODS

Although talc in the past has been mined to a large extent underground, the tendency is now more and more toward surface mining. Districts such as the Allamoore mining district in western Texas and that in the southwestern corner of Montana are virtually completely dedicated to open-pit mining. Vermont, which has in the past been dominated by underground mining [some of it to depths greater than 305 m (1,000 ft)], is now tending toward being almost completely open pit. The Gouverneur mining district in north-central New York, which until some 20 years ago was virtually totally an underground district, now has a significant proportion of open-pit mining. In the near future when special ores are found which have relatively minor competition from open-pit ores it will not be uncommon for them to be mined

underground; but when such a competitive edge is lacking, it is likely that open-pit mining will be considered.

GEOLOGY

Most talc deposits are stratiform and concordant with the enclosing rocks. Although they clearly show such tendencies, it is still nevertheless common for them to be called "veins." Although several types of origin are known, virtually all of the talc ores currently being mined are one of two types:

- 1) Deposits associated with sedimentary rocks.
- 2) Deposits associated with ultramafic igneous rocks.

Talc deposits are also associated with mafic igneous rocks such as gabbro, but this type of association is far more important re soapstone than talc and therefore will not be dealt with in this discussion.

The formation of talc is invariably epigenetic; talc ores are always of secondary origin.

Talc deposits formed by the alteration of sedimentary rocks generally have a carbonate precursor (siliceous dolomite being the most common), although to a much lesser degree magnesite and even limestone may also serve as the parent rock. The best example of this type of talc formation is that of the large district in the southwestern corner of Montana where all of the known commercial talc has been formed by the alteration of extremely old Precambrian dolomite (Olson, 1976).

Siliceous rocks may also be the precursor of talc ores, although this is far less common. Argillite, phyllite, quartzite, and schist are the major lithologic types in this category of sedimentary precursor.

Talc deposits associated with serpentinite and related ultramafic rocks such as dunite, peridotite, and pyroxenite are typified by the large talc mining district of central Vermont. Such deposits characteristically consist of a serpentinite core surrounded by a shell of talc-carbonate ore which in turn may be surrounded by a relatively thin shell of pure talc schist ore.

In the past, and even now to some extent, talc deposits derived from sedimentary rocks have dominated the US talc mining industry. This has been due in no small part to the fact that such ores may commonly be mined directly with no wallrock or included contaminants (i.e., "horses") and be milled directly on a dry basis. Those deposits associated with ultramafic igneous rocks, however, invariably must be beneficiated by wet methods (generally flotation) in order to obtain the high purity commonly achieved in products derived from the ores of sedimentary host rocks. The dry brightnesses of filler and extender products derived from ores of ultramafic igneous host rocks are generally considerably less than those of the products derived from sedimentary host rocks, particularly dolomites. Nevertheless, the tendency in recent years and probably for the immediate future is toward an ever-increasing importance of the position of the former ore types over those of the latter.

Most of the talc ores in the US have been formed in Precambrian rocks. This is invariably true in the Montana, New York, and west Texas districts and is generally true in the California-Nevada ("Death Valley") district. The talc ores of the Appalachians, however, have generally been

formed in Early Paleozoic rocks. In either case we are dealing with extremely old rocks which seldom crop out because such an enormous amount of tectonic uplift and subsequent erosion is necessary in order to bring them either to the surface or to place them at relatively shallow depths. Therefore, very few areas of limited geographical extent are capable of having commercial talc deposits, as opposed to most other industrial minerals ores such as clay, gypsum, limestone, phosphate, etc.

The geology of talc deposits in the US is described in great detail by Chidester, Engel, and Wright (1964).

The US currently has six talc mining districts. The geology of the five most important (production-wise) of these is briefly summarized.

California-Nevada

The California-Nevada talc mining district (also known as "Death Valley") is to all intents and purposes now dormant, due to a variety of reasons including cost factors and environmental constraints. It is about 322 km (200 miles) long and has an average width of 48 km (30 miles), although it locally may be as much as 121 km (75 miles) wide.

The district is too large and its geology too complicated to be satisfactorily summarized here, but essentially all of its deposits have been formed by metamorphism and hydrothermal replacement of siliceous and silicated magnesian marbles and limestones (Engel and Wright, 1960).

One deposit, the "Western-Acme" mine complex, extends for more than 1524 m (5000 ft) along strike, is as much as 24 m (80 ft) wide, and has been mined down dip for at least 107 m (350 ft).

Two main types of ore are present in this district: the "hard" ore of the miners which is markedly tremolitic, and the "soft" ore of the miners, which is talc schist. Many deposits contain both types, but the tremolitic ore is generally by far the more abundant.

In the early days most of the mining was performed underground, but in recent years there has been a pronounced tendency more toward surface operations.

Wright (1969) gives an excellent and detailed description of numerous mines and deposits in the central portion of the district.

Montana

The most important talc mining district in the US is that in the southwestern corner of Montana. This is currently the most important domestic source of tremolite-free talc ores from which pure and highly desirable products can be produced directly from crude ores without the need for beneficiation techniques, other than sorting.

The earliest significant geological investigation of the Montana talc mining district is that of Perry (1948), an excellent field study which was performed in the burgeoning days of the district. Olson (1976) describes the mines and deposits of the Ruby Range in more detail and Berg (1979) does so for the remainder of the district.

High-purity talc deposits in southwestern Montana, as presently known, are totally restricted in their occurrence to dolomitic marble in the Precambrian Cherry Creek Series. This generally white to pale green or yellowish-green talc commonly occurs as conformable lenses and stringers within the marble. Although structural controls in the strictest sense have not been recognized, the best talc bodies appear to occur spatially close to large bodies of granite gneiss.

The host rocks have been subjected to upper amphibolite grades of regional metamorphism which included the development of intense isoclinal deformation. Apparently the

formation of the talc occurred during the retrograde phase (greenschist grade) of the regional metamorphic event and it was almost certainly formed in Precambrian time.

Ross, et al. (1955) map the geological unit in which the talc has formed as covering an area about 290 km (180 miles) long east-west and 137 km (85 miles) wide (north-south), but the dolomitic marble which invariably hosts the talc does not occur within it over this entire extent.

The mechanism of the formation of Montana talc ore bodies was probably similar to that postulated by Van Horn (1948) for those similar talc ores in the Murphy, NC, area.

New York

The New York talc mining district was the site of the first talc mining in the US, which commenced about 1878. This district in the north-central portion of the state is the smallest in area of all the talc mining districts of the US, yet it appears to be dominant in its proven and probable ore reserves and it dominated domestic talc production for much of the early part of this century.

The talc-containing unit is a dolomitic marble which probably averages only 76 m (250 ft) wide or so in its least contorted areas; much greater widths, which may be locally observed to be as much as 610 m (2000 ft) thick, have probably been formed by structural flowage. Brown and Engel (1956) divided the rock sequence into 15 units, of which only unit 13 is known to contain ores. It is peculiar that this unit, which contains numerous deposits of talc and tremolite, is also the host for all of the well-known high-grade zinc deposits of the district. The talc and zinc ores, although they occur within the same unit, do not occur together.

Tremolitic ores have been proven by underground workings to down dip depths of at least 335 m (1100 ft) and by drill holes (sunk for zinc exploration) to down dip depths of more than 914 m (3000 ft).

Although pure talc schist has been found locally along the hanging wall contact between the tremolitic ore bodies and the overlying dolomite, these bodies have proven to be too erratic in their occurrence and too intensely secondarily stained to be exploited as ore.

Field mapping by workers of the US Geological Survey indicates that the tremolite, talc, and associated minerals were formed more than 10^9 years ago.

Although the talc ore zones locally pinch and swell, they are on the whole conformable with the enclosing dolomitic marble layers. The regional dip averages about 45° to the northwest; departures from this relatively simple structural framework are only locally significant. All of the rocks in this locality have been complexly folded and generally subjected to regional metamorphism of amphibolite grade.

Texas

Texas has two talc mining districts, the Llano district in the central part of the state and the Allamoore district in the western part of the state. The latter is the one most recently put into production and is now the only one of importance.

The Allamoore talc mining district extends along strike for about 32 km (20 miles) east-west and is up to 8 km (5 miles) wide. All of its ore deposits occur in the Allamoore Formation, which consists of thousands of feet of carbonate rocks, volcanic rocks, and phyllite (King and Flawn, 1953).

Not only is this district "one of a kind" within the US, it is also the one about which there is the least agreement as to its geology and the genesis of its ores. Some workers feel that phyllite is the host rock while others feel that the talc was formed by the replacement of primary sedimentary

magnesite. There appears to be little disagreement, however, that the talc formed in Precambrian time.

No ore body is known to have been "bottomed-out" by either drilling or mining. Talc is commonly found from the grass roots down and the soil cover is seldom greater than 0.3 m (1 ft) thick.

The ores for the most part are an extremely fine-grained admixture of dolomite and talc; beneficiation techniques for the recovery of pure talc have not yet been developed.

With the exception of a few small light-colored ore bodies, Texas crude ore is dark-colored, generally gray to black. With the sole exception of the volumetrically insignificant light-colored bodies, Texas talc ores have no possible uses as fillers and extenders, yet they serve as some of the finest ceramic crude ores known anywhere in the world, with superb pressing qualities and excellent firing characteristics.

Virtually all of the production has been from large open pits and the mining costs are certainly the lowest currently known in the US.

Vermont

Vermont has no carbonate-derived talc ores. Its ores have been formed from ultramafic bodies which have been locally serpentinized and then converted into talc and/or talc-carbonate mixtures. The talc deposits are commonly associated with dunite, peridotite, and serpentinite, which were probably the precursors of the talc itself.

The talc ores are generally dark-colored and are relatively high in iron content, particularly near the surface where weathering processes have concentrated the iron. Although the mineral talc is commonly a major constituent, the grades of Vermont talc ores are generally considerably lower than those of most of the other US talc mining districts.

In northern Vermont entire ultramafic bodies have been converted into talc-carbonate ore mixtures which may have widths on the order of 30.5 m (100 ft) or so. In southern Vermont a similar body has a width of about 53 m (175 ft). At least 145 separate talc occurrences are known in central Vermont within an area having a strike length of about 241 km (150 miles) (north-south) and an east-west width ranging from 8 to 40 km (5 to 25 miles).

To manufacture the most profitable product line, i.e., high-purity tremolite-free talc products, it is always necessary when using Vermont talc ores to employ froth-flotation techniques. Although the resulting products do not approach those from Montana or New York on a dry brightness basis, the manufacture of such products is quite profitable. In the past, several Vermont talc producers, however, have commonly ground the talc ore as mined and then simply subjected that ground product to size-classification techniques, thereby producing low-value dusting compounds and fillers for roofing products and for the rubber industry.

GENESIS

Talc is always of secondary origin. Those ores derived from sedimentary host rocks have generally been formed by metamorphic or metasomatic processes associated with regional high-grade metamorphic alteration. In several instances the formation of the talc ores has occurred during the retrograde metamorphic events associated with such metamorphism which attained grades as high as amphibolite rank. Those ores derived from ultramafic igneous rocks have generally been formed by the reaction between serpentinite and introduced CO₂.

STRUCTURAL CONTROLS

Most talc ore bodies are stratiform in habit, being more or less concordant with their enclosing tabular rock units.

Therefore they are in essence tabular ore bodies and commonly relatively easy to mine. In many instances, however, structural deformation may have been intense, resulting in the development of isoclinal folding and a distinct tendency for the ore body to noticeably pinch and swell, both along strike and dip. Later block faulting may also locally complicate the task of the talc miner. Developmental and production-exploration drilling, which is seldom performed due to a variety of reasons, is nevertheless desirable with virtually all talc deposits, more for the need to know whether folding or faulting may have displaced or otherwise modified the distribution of the talc body than toward the need for knowledge of grade control. In the past most talc miners have just shot off the next round and hoped that they stay in ore; this technique (or lack of same) is changing, albeit very slowly, toward a more enlightened attitude.

EXPLORATION

In the exploration phase it is most important to recognize that talc is extremely limited as to which ages of geologic formations it may occur within as potentially commercial bodies. The next stage of such an effort should be a thorough literature search coupled with visits to governmental and academic institutions where past or present workers may have been pursuing investigations into talc and related mineral occurrences. The use of unpublished open-file materials is important here. Lastly, known deposits should be visited and studied in order to more intelligently guide the search for their currently unknown analogues.

Once the actual physical sites deemed to be most favorable for physical exploration have been chosen, it must be realized that the life of a talc exploration geologist is tremendously complicated and made extremely difficult due to the tendency of talc to almost never crop out! It is not at all unusual for such explorationists to literally have to get down on their hands and knees and then study float fragments commonly considerably smaller in size than one's fingernail. The mapping of the areal patterns of the most abundant type of float rock may then be extrapolated into the compilation of bedrock geologic maps. These maps may then be used to guide exploration trenching with the backhoe or bulldozer across the mapped zones of talc-related rock types.

Drilling may then be performed after the presence of interesting quantities of talc or talc-related alteration has been observed and mapped in the trenches. Core drilling is always preferred on the first pass, because with it the nature and distribution of both talc and its associated impurities can be detected without question. On subsequent drilling phases, reverse circulation methods on closer spacings may be employed.

Geophysical and geochemical methods have not yet proven to be very successful in the exploration for talc. Soil-sampling methods, however, have proven their worth in both Alabama and Montana. Such techniques may vary widely in the details of the actual procedures followed, but essentially the soil is sampled, generally with a hand-operated soil auger, and the resulting samples are then processed and studied in the laboratory, where they are carefully sized and then subjected to X-ray diffraction.

25. Titanium*

Elemental titanium has become famous as a space age metal, because of its high strength/weight ratio and resistance to corrosion. However, the major use is in the form of titanium dioxide pigment, which because of its whiteness, high refractive index, and resulting light-scattering ability, is unequaled for whitening paints, paper, rubber, plastics, and other materials. A relatively minor use is in welding rod coatings, in the form of the mineral rutile. The only commercially important titanium ore minerals at the present time are ilmenite and its alteration products, and rutile.

Titanium was discovered by Gregor in 1790, as a white oxide which he discovered from menaccanite, a variety of ilmenite occurring as a black sand near Falmouth, Cornwall. Barksdale (1966) stated that the fundamental chemical reactions on which the present-day titanium industry is based were known before 1800, although it was not until 1918 that these pigments were available commercially on the American market.

Pings (1972) outlined the early history of the titanium industry in the United States, referring to the work of Guise (1964) and others:

Mining of titanium minerals in the United States began sometime between 1880 and 1900, in Chester County, Pennsylvania. Small quantities of rutile were also produced during that time in North Carolina and Georgia. In 1901 rutile was mined from a deposit near Roseland, VA, and was used in making titanium chemicals and for coloring ceramics. Ilmenite in the deposit was produced as a separate item in 1913, and rutile and ilmenite were obtained from this deposit through 1921.

The mining of titanium bearing beach sands began in 1916 near Mineral City and Pablo Beach, FL, for the purpose of making titanium tetrachloride to be used in tracer bullets, flares, and smokescreens. The titanium pigment industry was founded in 1918. By 1928 a large part of the domestic production of rutile, ilmenite, and zircon came from Florida. However production ceased in 1929 in Florida with the mining of newly discovered deposits in Virginia which were mined until 1968. The discovery of new deposits in Florida, and the development of better mining and concentrating methods for lowgrade sands, led to a return of activities in this area. The large deposits near Tahawus, NY, were brought into production in 1942 by National Lead Co. (now NL Industries, Inc.), and by 1949 this company was the leading producer of ilmenite in the world. In 1948 the extensive deposits of ilmenite and ilmenite-bearing iron ores were discovered in eastern Quebec.

The large Trail Ridge sand deposit in Florida was discovered by E.I. du Pont de Nemours & Co., Inc. geologists in cooperation with the US Bureau of Mines and the Florida Geological Survey, and was developed by Du Pont in the late 1940s (Garnar, 1980).

The beginning of the modern titanium metal industry was in 1948, when Du Pont produced the first metal. US Bureau of Mines reports, which gave details of the Kroll process, together with the attractive properties of the metal for military aircraft, led to a concerted effort by industry and government to develop a large-scale titanium metal industry, which reached a peak capacity of over 36,000 stpy from six producers by 1958 (Pings, 1972a).

The major developments affecting the titanium metal industry since the late 1950s have been fluctuations in the

production rate of military aircraft, and the increasing use of the metal in commercial aircraft and for industrial applications. A major change in the titanium dioxide pigment industry starting in 1957 was the development and expansion of the chloride process, which generally uses higher grade TiO_2 raw materials such as rutile in contrast to the relatively low TiO_2 ilmenite feed used in the older sulfate process. The resulting increased demand for rutile led to higher prices, which in turn stimulated the development of processes for making rutile substitutes by beneficiation of ilmenite.

Since 1960, new deposits of sand ilmenite were developed in New Jersey, Georgia, and Florida.

GEOLOGY

Mineralogy

Although titanium is the ninth most abundant element of the lithosphere, comprising an estimated 0.62% of the earth's crust, there are only a few minerals in which it occurs in major amounts: rutile, anatase, and brookite (which are polymorphs of TiO_2), ilmenite and its alteration products, including leucoxene, perovskite (CaTiO_3), and sphene (CaTiSiO_5). Anatase may be emerging as a significant ore mineral of the future, but ilmenite, altered ilmenite, leucoxene, and rutile have been the only large volume ore minerals through 1980.

Ilmenite: The chemical formula of theoretically pure ilmenite is $\text{FeO} \cdot \text{TiO}_2$. It was shown by Ramdohr (1950) that up to 6% Fe_2O_3 may be dissolved in solid solution, and at 1050°C a continuous solid solution series exists between ilmenite and hematite (Nicholls, 1955). Hematite may, and often does, occur with ilmenite as minute exsolution lamellae. Magnesium and manganese may substitute for the ferrous iron in ilmenite, which can produce the rare end-members MgTiO_3 (geikelite) and MnTiO_3 (pyrophanite), but usually these two elements are present as minor impurities. Magnetite is a common associate of ilmenite in igneous and metamorphic rocks, and in such coexisting pairs chromium, nickel, and vanadium tend to concentrate in magnetite while manganese concentrates in ilmenite.

In basic igneous rocks, notably anorthosites, gabbros, and basic lavas, ilmenite frequently occurs in intimate intergrowths with magnetite. The ilmenite forms lenses following octahedral parting planes in the magnetite host, and magnetite may, in turn, form crystallographically oriented inclusions within the ilmenite lenses.

Altered Ilmenite and Leucoxene: In sand deposits ilmenite frequently exhibits a degree of alteration caused by oxidation and removal of iron. The end product is essentially TiO_2 . The process was described by Temple (1966).

Alteration is an extremely slow process that is aided by elevated temperature, so that older sand deposits in temperate and tropical regions of the world generally contain high- TiO_2 ilmenite. Younger deposits, for example, those found on modern beaches, and those in the higher latitudes usually contain unaltered ilmenite with a TiO_2 content around 50%, near the theoretical level for pure ilmenite.

Rutile: Rutile, the high pressure, high temperature polymorph of TiO_2 , is the commonest form in nature and is a widespread accessory mineral in high grade metamorphic gneisses and schists and in igneous rocks. It is also a common detrital mineral.

*Excerpt from Lynd, L.E., and Lefond, S.J., 1983, "Titanium Minerals," *Industrial Minerals and Rocks*, 5th ed., Vol. 2, S.J. Lefond, ed., AIME, New York, pp. 1303-1362.

Commercial rutile concentrates run 95% TiO_2 or more, with SiO_2 , Cr_2O_3 , V_2O_5 , Al_2O_3 , and iron oxides comprising the remainder. Analyses of rutile from other occurrences may show major amounts of tantalum and columbium, which can enter titanium minerals because of the close similarity in ionic radius between Ti^{+4} and both Cb^{+5} and Ta^{+5} . There is also a high iron variety termed ferroan rutile.

Rutile may form by alteration from ilmenite or anatase, and while it is very stable over a broad range of geologic conditions, occasionally processes may be reversed so that rutile alters to sphene, possibly ilmenite, and more rarely anatase.

The characteristic color of rutile is reddish brown, but it may be black, violet, yellow, or green.

Classification of Deposits

Titanium minerals have been mined from both rock and sand deposits. Until about 1942, nearly all of the ilmenite and rutile produced commercially came from sand deposits, but about one third of the world's ilmenite in 1982 came from rock deposits. Rutile, however, is now produced exclusively from sand deposits.

Rock Deposits: *Anorthositic Deposits*—Nearly all of the known commercially important rock deposits of titanium minerals are associated with anorthositic or gabbroic rocks, and are of three main types: ilmenite-magnetite (titaniferous magnetite), ilmenite-hematite, and ilmenite-rutile. Ilmenite-magnetite deposits usually contain ilmenite and magnetite as granular intergrowths that can be separated rather readily to yield concentrates of ilmenite and magnetite which may be essentially homogeneous minerals, or may consist of intimate intergrowths of one mineral in the other. Ilmenite-hematite deposits usually contain these minerals as intimate intergrowths and yield an ilmenite-hematite, or hemo-ilmenite concentrate rather than a separate concentrate of each mineral. Ilmenite-rutile deposits contain rutile and ilmenite either as separate concentrations or occurring together.

Miscellaneous Deposits—Other types of rock deposits in the United States that have been mined, or seriously considered as sources of titanium, include a deposit of ilmenite disseminated in schist in Yadkin Valley, North Carolina (Broadhurst, 1955), and a complex deposit of rutile, anatase, and brookite in a pegmatitic phase of alkalic rocks surrounding sediments at Magnet Cove, AR (Fryklund and Holbrook, 1950; Fryklund, et al., 1954).

A perovskite deposit in southwestern Colorado owned by Buttes Gas & Oil Co. was estimated to contain about 50 million tons of TiO_2 (Thompson, 1977). Processes to convert perovskite to titanium dioxide were being investigated through 1982.

The US Bureau of Mines (Llewellyn, et al., 1980) and the US Geological Survey (Force, 1980) investigated the porphyry copper ores and mill tailings as a possible source of rutile. It was concluded that this material, which contains about 0.3% of potentially recoverable fine-grained rutile, could constitute a sizable domestic resource, but more work is needed to develop an economic recovery process.

Major occurrences of anatase and ilmenite in weathered carbonatite bodies at Tapirå, Salitre, and Catalão in Minas Gerais, Brazil, are under investigation as new raw material sources. Feasibility and pilot plant studies to determine grades and recoveries of possible future commercial titanium mineral concentrates have been carried out. Modifications in pigment manufacturing processes may be necessary to accommodate potential production as a feed, or beneficiation or slagging may be used to make concentrates acceptable to

existing pigment plants, but successful exploitation by any avenue will cause these and possibly other carbonatite occurrences to be classed as an important rock ore type.

Occurrences of titanium minerals in other types of rocks are known, but are not considered to be of commercial significance (Force, et al., 1976).

Sand Deposits: Beaches, bars, dunes, and stream sands in many parts of the world are enriched by gravity segregation of the heavy minerals that are chemically resistant to weathering and physically hard enough to withstand considerable abrasive action. The energy of currents, waves, and to a lesser extent, winds, mobilizes the sand grains and permits them to behave as individuals within a fluid medium. Where the energy decreases, the heavier particles fall out while the lighter ones are carried farther. The composition of the heavy mineral concentrate depends on the nature of the geologic terrane being subjected to weathering and erosion and supplying materials to transporting streams. If available at the source, titanium-bearing minerals, zircon, magnetite, chromite, rare earth minerals such as monazite, staurolite, kyanite, sillimanite, garnet, xenotime, precious metals, and diamonds may be concentrated in this way. The resultant gravity segregations are usually dark colored and are called "black sands." Not all black sands are ore mineral occurrences; those found on the beaches of volcanic islands, for example, may be mostly amphibole and pyroxene.

There is a wide variation in titaniferous black sands in terms of heavy mineral concentration, percentage of titanium minerals within the heavy mineral suite, and TiO_2 content of the titanium mineral concentrate. All of these factors interact in rating deposits according to quality and as to whether they are today's reserves or possible resources of the future. Furthermore, the presence or absence of valuable coproduct or byproduct minerals such as zircon is a complicating factor.

Sand deposits in which rutile is the only economically important titanium mineral occur along the eastern shore of Australia. Ilmenite, altered ilmenite, and rutile form inland elevated strand-line deposits in Western Australia and in older sands of the Atlantic Coastal Plain of the United States. Ilmenite and altered ilmenite are the principal titanium ore minerals in other Western Australian districts; in Kerala, India; in deposits north of the Black Sea in the USSR; and in Florida and Georgia. Relatively unaltered ilmenite is found in large beach and dune occurrences along the northeastern coast of South Africa, in the Nile Delta of Egypt, and in still other Western Australian deposits, those closest to the present coast. Sand deposits of titaniferous iron ores occur as dune and beach deposits in many volcanic areas, of which those in New Zealand are the outstanding examples.

Mode of Occurrence and Origin

Rock Deposits: The anorthositic deposits contain titanium minerals either as massive ore, or disseminated in rock ranging from anorthosite to gabbro in composition, and varying in grade from solid ore to almost barren rock. While there are metamorphic and hydrothermal features in some parts of these deposits, for the most part, they seem to have formed at magmatic temperatures by magmatic processes.

The only other type of ilmenite rock deposit to be exploited commercially was the Yadkin Valley deposit in Caldwell County, North Carolina (Broadhurst, 1955), which was operated by a Glidden Co. subsidiary from 1942 to 1952. The ore consists of small masses of ilmenite disseminated throughout a talcose body which lies conformably with the enclosing quartzite and mica schist.

The Hot Spring County, Arkansas, deposits have been studied extensively for possible commercial development, and some rutile was recovered from the Magnet Cove deposit from 1932 to 1944. The deposits occur in a complex mixture of alkalic igneous rocks intruding folded sedimentary and metamorphic rocks. Much of the titanium is in the form of rutile or brookite, but many other titanium minerals have been identified. The ore minerals are intimately associated with gangue (Fryklund and Holbrook, 1950; Fryklund, et al., 1954; Toewe, et al., 1971).

Sand Deposits: Titanium-bearing black sands are found mainly in ancient or modern ocean and sea beaches around and occasionally within continental land masses. They frequently form highly visible surficial layers between the high and low water marks which may extend intermittently along coasts for miles, but such concentrations, containing perhaps 80% heavy minerals, are not mined on a large scale because they are usually too shallow and narrow to represent major reserves. Minal bodies are multilayered occurrences of a similar nature left behind by retreating seas, or coastal dunes formed when heavy minerals from black sand beaches were being transported inland by wind action. Heavy minerals tend to be disseminated within such dunes rather than layered as in beach-type deposits.

The history of a black sand ore body may be simple or complex. The essential elements are: (1) a "hinterland" of crystalline rocks in which the heavy minerals were accessory constituents, (2) a period of deep weathering, (3) uplift with rapid erosion and quick dumping into the sea of the products of stream erosion, and (4) emergence of the coastline with longshore drift and high-energy waves acting during the process of shoreline straightening. There may be intermediate stages such as partial concentration of the heavy minerals in a coastal plain sediment and subsequent elevation, erosion, and reconcentration. The sand brought to the sea by rivers is picked up and carried away from their mouths by longshore currents, forming offshore bars and filling in bays between headlands, particularly during storms. Where bars are formed, the sand-carrying waves drag bottom and lose their energy so that the heavy minerals fall on the seaward side while the light minerals are cast over the bar and into the quieter water beyond. Layer upon layer of varying concentrations of heavy minerals accumulates on the growing bar in this way. Where bays are being filled with sand, both heavy and light minerals are churned from the bottom by landward-rushing waves and are hurled up the beach slope. The smoother, slower retreat of each wave mobilizes the uppermost layer of sand deposited there, and draws away the light minerals, to be picked up again and again by waves as currents move them along the coast, while leaving the heavy minerals behind. Alternating periods of stormy and calm weather leave alternating layers of high and low concentrations of heavy minerals in the beach sand as it advances toward the sea.

DISTRIBUTION OF DEPOSITS

Reserves

Ilmenite resources in rock and sand deposits in the United States, recoverable under the economic and technological conditions of 1981, were estimated to contain 18 million tons of titanium dioxide. Rock deposits in New York account for 29% of the total. The remainder is in beach and river sands in Florida (Garnar, 1980), Georgia, New Jersey (Markewicz, 1969), and Tennessee. An additional 94 million tons of titanium dioxide in ilmenite and 48 million tons in perovskite

(Thompson, 1977), not recoverable under present conditions, occur in identified resources, widely dispersed throughout the United States. Major occurrences lie in Colorado, Minnesota, New Jersey, New York, and Wyoming.

Reserves of rutile in the United States are in sand deposits in Florida, Georgia, and Tennessee. The rutile in these deposits contains about 1.7 million tons of titanium dioxide. Identified but presently subeconomic deposits in Arizona, Arkansas, California, Florida, North Carolina, South Carolina, Tennessee, Utah, and Virginia contain an estimated 13 million tons of titanium dioxide in the form of rutile. The rutile in the Arizona and Utah resources occurs mainly as an accessory mineral in porphyry copper ores and mill tailings (Force, 1980; Llewellyn and Sullivan, 1980).

Estimates for world titanium reserves and resources are shown in Table 1. World reserves of ilmenite are estimated to contain 266 million tons of titanium dioxide, of which US reserves account for 7%. The titanium dioxide content of world rutile reserves is estimated at 97 million tons; US reserves represent 1.6% (Lynd, 1983).

Rock Deposits—Principal Producing Countries

United States: *Sanford Lake District, New York*—The Sanford Lake deposits (Gross, 1968), are located in the heart of the Adirondack Mountains. Discovery of these titaniferous magnetite deposits dates back to 1826. Several attempts to exploit the ores for iron prior to 1942 proved uneconomical because of difficulties with the associated titanium, and the isolated location (Bachman, 1914; Masten, 1923). The district is within the large anorthosite massif making up the central high peak area of the Adirondacks. All of the various low silica rock types associated with the massif are found within the boundaries of the district. These consist of both the Marcy and Whiteface types of anorthosite and of gabbroic anorthosite, gabbro, and different grades of titaniferous magnetite ores. All of the rocks contain the same minerals and differ only in the percentages of these constituents.

There are four mineralized areas where an economic grade of ore has been found. Three of these have both gabbroic-type ore and anorthositic-type ore. The fourth has only gabbroic ore. The TiO_2 contents of the ores range from 9.5 to over 30.0% TiO_2 . Ore bodies of both types are related to gabbro and conform to the configuration of the gabbro bodies within the anorthosite.

**Table 1. World Reserves of Ilmenite and Rutile
Thousands of Short Tons of TiO_2 Content**

Country	Ilmenite	Rutile
Arab Republic of Egypt	—	—
Australia	27,000	10,000
Brazil	2,000	67,000*
Canada	26,000	—
China	34,000	—
Finland	3,400	—
India	22,000	3,000
Norway	52,000	—
Sierra Leone	—	3,000
South Africa, Republic of	57,000	5,500
Sri Lanka	21,000	5,000
United States	18,000	1,700
USSR	7,000	3,000
Total	270,000	140,000

*Mainly anatase. Metric equivalent: $1\text{st} \times 0.9071847 = 1\text{t}$.

Except for a few thousand tons mined before 1900, all ore production has come from the Sanford Hill-South Extension ore body. Mining began on Sanford Hill in 1942, and as a result of further exploration and development work, was transferred in the early 1960s to the South Extension part of the ore body, which was overlain by glacial till and Sanford Lake.

GENERAL GEOLOGY. Rocks of the Sanford Lake district are regarded as members of a genetically related anorthositic series, the whole being part of the large Adirondack anorthosite massif. Locally, anorthosite grades into gabbro by an increase in the content of mafic minerals. Buddington (1939) divided this sequence into four rock types depending upon the amount of ferromagnesian minerals present: anorthosite with 0 to 10%, gabbroic anorthosite with 10 to 22.5%, anorthositic gabbro with 22.5 to 35%, and gabbro with over 35% mafic minerals.

For mine mapping purposes, rock types are designated as anorthosite, gabbroic-anorthosite, gabbro, and the various grades of ore.

ECONOMIC GEOLOGY. The titaniferous magnetite ore bodies of the district are of two types. One type, referred to locally as "anorthositic ore," is associated with anorthosite waste rock as coarse-grained massive lenses of irregular shape, with little structure and having sharp contacts with the anorthosite. The second ore type, "gabbroic ore," occurs as fine to medium grained oxide-enriched bands within the gabbro, with well defined structures similar to those in the gabbro. Contacts with the gabbro range from distinct to gradational.

In the Sanford Hill-South Extension ore body, both types of ore occur. The anorthositic type forms a footwall ore body and the gabbroic ore forms a hanging wall ore body. These are separated by various widths of anorthosite and/or gabbro rock. In some instances the two types of ore are in direct contact.

MINERALOGY OF THE ORE BODIES. The ores of the Sanford Lake district contain both ilmenite and magnetite as granular aggregates and disseminated grains. The ratio of total Fe: TiO_2 is generally 2:1 or greater in the anorthositic ore, and is less than 2:1 in the gabbroic ore. Gabbroic ore is finer-grained than anorthositic ore.

The magnetite grains are seldom homogeneous, and normally contain some ilmenite in solid solution and up to 35% of ilmenite as exsolution intergrowths. The intergrown ilmenite occurs as tabular plates oriented parallel to the octahedral planes of the magnetite or along the boundary between magnetite grains.

A second highly magnetic phase, ulvospinel (Fe_2TiO_4), has been identified as a fine network within the magnetite of the Sanford Hill-South Extension ores. This ulvospinel was first identified by Ramdohr (1956), using high magnification metallography. Kays (1965) used X-ray techniques along with chemical assay data to estimate that the magnetite grains may have an ulvospinel content of 34%.

About 0.5% vanadium occurs in solid solution within the magnetite. No separate vanadium mineral has yet been identified.

Ilmenite occurs as a matrix around magnetite and is observed under the microscope to be corroded by magnetite. It is finer-grained than magnetite and can be distinguished megascopically in coarse-grained anorthositic ore by its high luster and conchoidal fracture, compared to the dull luster and parting planes in magnetite. In finer-grained ore, the ilmenite and magnetite are more equigranular and cannot be recognized individually in hand specimens.

Other minor minerals identified in the Sanford Hill-South Extension ore body include chalcopyrite, sphalerite, molybdenite, prehnite, barite, leucoxene, scapolite, epidote, orthoclase, and quartz.

ORE GENESIS. Investigators have generally considered the Sanford Lake ores to have formed by magmatic segregation, as a result of such processes as simple segregation, filter-pressing of residual liquid with injection into the wall rock, and gravitational purification of the oxide melt by floating out of crystallized silicates with later injection, with replacement playing a minor role (Balsley, 1943; Bateman, et al., 1951; Buddington, et al., 1955; Evrard, 1949; Osborne, 1928; Stephenson, 1945). Gillson (1956), however, related the variations in the anorthosites and the origin of the gabbro and ore to a series of pneumatolytic replacements involving andesination of Marcy anorthosite. Later solutions were assumed to be the source of the ferromagnesian and ore minerals.

Heyburn (1960) made reference to two stages of gabbro emplacement, one of them associated with the anorthosites, and the second a gabbroic intrusive rich in iron and titanium with sufficient volatiles to allow partial replacement of anorthosite by ore minerals.

Kays (1965) proposed that during granulation and shearing of the anorthosite, calcium and aluminum were released from the original laboradorite plagioclase, resulting in andesination, but by a different means than proposed by Gillson (1956). Creation of pressure gradients by rock fracturing was then postulated to cause iron, magnesium, and titanium to migrate to the low pressure fractured areas, where they reacted with the calcium and aluminum released by andesination to form ferromagnesian silicates, garnet, ilmenite, and magnetite. The resulting replacement could be partial, as in gabbro, or complete over large volumes as in anorthosite.

Sun (1971) concluded that the Cheney Pond deposit is more likely to be of magmatic rather than replacement or metamorphic origin, stressing evidence of magmatic crystallization temperatures and the layered nature of the ore bands, which resembles the structure of ultramafic stratiform sheets.

Virginia Titanium Deposits—The titanium ores of Virginia are also associated with anorthosite, and are of two types: (1) rutile and ilmenite disseminated in the border facies of the anorthosite and bordering gneiss, and (2) rutile and/or ilmenite with apatite in the form of dike-like masses which Watson and Taber (1913) named nelsonite after the county in which they are most common. Deposits of both types have been mined commercially, utilizing mainly the soft, saprolite portions of the ore bodies which form an upper layer about 9 to 37 m (30 to 120 ft) thick.

Rutile was first mined commercially at Roseland, VA, in 1900 by the American Rutile Co. The ore was obtained by open cut mining of both saprolite and hard rock. The mine was operated intermittently until 1949 when increased labor costs, low grade ore, and low market prices for rutile led to a shutdown of operations. The ore consists almost exclusively of disseminated rutile in the anorthosite (Fish, 1962; Hillhouse, 1960).

Commercial surface mining for ilmenite began in 1930 from a large saprolite ore body along the Piney River on the old Warwick Tract. This mine was first operated by the Vanadium Corp. of America, and later by the Southern Mineral Products Corp. (Hillhouse, 1960) until it was acquired by the American Cyanamid Co. in 1944. In 1958 the company transferred operations to the deposit on the S.V. Wood

property near Lowesville about 5 km (3 miles) to the west (Fish, 1962), supplying ilmenite to its nearby sulfate process pigment plant until 1971, when both mine and pigment plant were closed down, mainly because the supply of readily mined soft ore at this location was running out.

Fish (1962) estimated the saprolite deposits in the area to contain reserves of titanium-bearing material in excess of 20 million tons, averaging 7.0% TiO_2 . Unweathered rock beneath the saprolite contains comparable titanium values, but mining and processing this ore would be more expensive. The ore is derived from two types of rocks; one, containing ilmenite as the dominant titanium mineral, is a diorite, and the other, containing ilmenite and rutile, is an anorthosite.

The nelsonite deposits are higher grade, but of limited size. Many of them are lenticular and pinch out at shallow depths (Fish and Swanson, 1964).

Davidson, et al., (1946) studied the Piney River deposit and concluded that it was emplaced as a large dike fingering into its walls. Replacement was agreed to have occurred, but this was not regarded as proof that the main development of ore was by replacement.

Theories proposed regarding the origin of the Virginia titanium ores in general include magmatic segregation from the anorthosite, favored by Watson and Taber (1913); differentiation from a granodiorite magma, suggested by Moore (1940); and replacement by invading solutions, proposed by Ross (1941, 1947) and Hillhouse (1960).

Yadkin Valley Deposit, North Carolina—The Yadkin Valley deposit is about 21 km (13 miles) north of Lenoir, in Caldwell County. The ore occurs as a series of narrow, close-spaced lenses which form a nearly continuous vein about 305 m (1000 ft) long. The ore consists of small masses of ilmenite disseminated throughout a talcose body which lies conformably with the enclosing quartzite and mica schist (Broadhurst, 1955). Some rutile occurs as fine inclusions in the mica, but was not recovered.

The ore zone is parallel to the gneissic structure, is about 9 m (30 ft) thick, and was mined by quarrying, running about 30 to 35% TiO_2 . The mine was operated from 1942 to 1952 by the Yadkin Mica and Ilmenite Co., a subsidiary of Glidden Co. A flotation ilmenite concentrate was produced which contained 49 to 52% TiO_2 (McMurray, 1944), unusually high grade for a rock ilmenite.

Hot Spring County, Arkansas Deposits, (Magnet Cove, Christy, Hardy-Walsh)—These deposits occur in a complex mixture of alkaline igneous rocks intruding folded sedimentary and metamorphic rocks, many of which contain various quantities of titanium-bearing minerals (Fryklund and Holbrook, 1950). Much of the titanium is in the form of rutile or brookite, but many other titanium minerals have been identified. Rutile was recovered commercially from the Magnet Cove (Reed, 1949a) deposit from 1932 to 1944. A considerable amount of work has been done on ore dressing techniques for these ores (Fine and Frommer, 1952; Fine, et al., 1949). The features contributing most to the difficulty of utilizing these deposits are their comparatively low grade, the larger deposits averaging 3 to 6% recoverable TiO_2 (Fryklund, et al., 1954), the formation of large amounts of slimes during grinding, and the intimate association of ore minerals and gangue, resulting in low recoveries and comparatively low grade concentrates (Toewe, et al., 1971). No commercial output of titanium minerals has been reported from the Christy (Reed, 1949) or Hardy-Walsh deposits.

Other US Deposits—Other deposits of potential commercial importance include the titaniferous magnetite de-

posits in the Laramie Range, Wyoming (Diemer, 1941; Frey, 1946; Pinnell and Marsh, 1954). Metamorphic rocks were intruded by anorthosite, which in turn was cut by gabbro and titaniferous magnetite dikes. The main dike at Iron Mountain consists of a granular aggregate of homogeneous ilmenite and magnetite containing very small intergrown ilmenite inclusions. In the Taylor deposit, as much as 60% apatite is locally present. Resources of high grade ore containing about 45% Fe and 20% TiO_2 may amount to about 30 million tons. Further metallurgical research would be needed, and the geographical location is at present unattractive for commercial development.

Other large deposits occur in the San Gabriel Mountains in Los Angeles County, California, as disseminations in a gabbroic facies of an anorthosite (Moorhouse, 1938). Very large tonnages may be available, but the average grade is only about 4.5% TiO_2 .

Smaller deposits occur in nearly every one of the western states, for example in Montana (Wimmler, 1946); Minnesota (Broderick, 1917); Wichita Mountains of Oklahoma (Merritt, 1939); Boulder County, Colorado (Jennings, 1913); and the San Juan district, Colorado (Singewald, 1913).

Canada: Quebec—The geology and general characteristics of the Canadian titanium deposits were well described in an extensive and thorough report by Rose (1969). He concluded that the titaniferous magnetite and ilmenite deposits in eastern Canada were formed by magmatic differentiation and injection, mainly in Precambrian time, presumably from 850 million to 1500 million years ago. There is an unmistakable genetic relationship between these deposits and anorthositic rocks. The anorthosite bodies, as exemplified by the Morin, St. Urbain, Lac St. Jean, Sept-Iles, and Lac Allard anorthosites, appear in general to be composite, multiple intrusions composed mainly of anorthositic and gabbroic (noritic) rock.

The main deposits include: the sill-like Lac Tio ilmenite-hematite deposits being mined by QIT-Fer et Titane, Inc. (formerly Quebec Iron and Titanium Corp.), estimated to hold about 100 million tons of high grade open pit material; the dikelike Magpie Mountain medium grade titaniferous magnetite deposits, averaging 43% iron and 6% titanium, probably containing over 250 million tons of open pit material; the St. Urbain deposits with over 20 million tons of high grade ilmenite-hematite; and several million tons of slightly lower grade material near Ivry, and in the Lac du Pin-Rouge area, near St. Hippolyte-de-Kilkenny. Substantial amounts of low-grade titaniferous magnetite and ilmenite occur at many other localities in the Morin, Lac St. Jean, Sept-Iles, Lac Allard, and St. Urbain anorthosite areas (Rose, 1969).

Kish (1972) studied the chemical composition of the Quebec deposits, particularly with regard to the vanadium content, and reported that vanadium concentrations of economic importance have so far been found only in the titaniferous magnetite deposits. The composition and origin of selected titaniferous deposits were discussed by Lister (1966).

ALLARD LAKE (LAC TIO) DEPOSITS. The geology of the area in which the Allard Lake deposits occur was investigated by Retty (1944), who noted numerous concentrations of ilmenite within a mass of anorthosite, along the shores of several lakes. These ilmenite showings, while not large enough to warrant commercial development, led to detailed exploration of the anorthosite area in 1946 by Kennco Explorations, Ltd., which resulted in the discovery of the large Lac Tio deposit. The deposit lies between Allard Lake and

Puyjalon Lake, about 40 km (25 miles) north of Havre St. Pierre on the north shore of the St. Lawrence River.

The geology of the area and the nature of the ilmenite deposits have been well described by Hammond (1949, 1952), and by Hargraves (1959). The most important lithological unit in the area is the Allard Lake anorthosite. It is one of several anorthosite masses occurring at intervals in the southeastern part of the Precambrian shield, in a line trending northeast from the Ontario-Quebec boundary to the Labrador coast. The Allard Lake anorthosite mass is about 145 km (90 miles) long, and 32 to 48 km (20 to 30 miles) wide, its length paralleling the Gulf of St. Lawrence. The several facies of the anorthosite range from almost pure feldspar rock through anorthositic gabbro, ilmenite-rich anorthosite, and norite. The norite occurs as steeply dipping sheets, as much as 6 km (4 miles) long and 914 m (3000 ft) thick, intruded into the anorthosite, and is rich in hematite and magnetite.

The Lac Tio deposit is a flat-lying, tabular body about 1097 m (3600 ft) long, and 1036 m (3400 ft) wide. With an estimated tonnage of 125,000,000 st of ilmenite averaging 32% TiO₂ and 36% Fe, it is the largest known ore body of its type in the world.

The ore consists of exsolution intergrowths of ilmenite and hematite, with coarse-grained ilmenite containing numerous blades and lenses of hematite up to 0.3 mm wide, which in turn may contain similarly shaped but smaller inclusions of ilmenite, in parallel orientation. The typical high grade ore contains about 75% ilmenite, 20% hematite, and 5% gangue minerals consisting of pyroxene, feldspar, and minor amounts of pyrite, pyrrhotite, and chalcopyrite.

The ore occurs in anorthosite and anorthositic gabbro and is identical in character with that in other deposits in the area. Inclusions of anorthosite are found in the ore, and do not show evidence of replacement by ilmenite. The ilmenite is very coarse-grained along its contacts with anorthosite, and the contacts are very sharp. Tiny dikelets of coarse granular ilmenite commonly cut the anorthosite at contacts with the ore bodies. On a basis of such direct field evidence, Hammond (1949, 1952) concluded that the Allard Lake ores are late magmatic, probably emplaced by a process of late gravitational liquid accumulation, with injection of the oxides into fractures within the anorthosite.

The ilmenite-hematite ore produced from the Lac Tio operation contains about 34% TiO₂ and 40% Fe. Because of its high iron content it is not used directly for titanium dioxide pigment manufacture, but is subjected to further concentration and electric furnace smelting at Sorel, Que., to produce iron metal, and a high-TiO₂ slag which is widely used as a feed for sulfate process pigment plants.

China: The largest titanium deposit in China is reportedly the 1.1 billion ton Panzihua titaniferous magnetite deposit containing about 7% titanium in the form of ilmenite, near Dukou, Sechuan province (Brady, 1981).

Norway: The iron-titanium provinces of Norway have been described by Geis (1971), Vokes (1968), Carstens (1957), Michot (1956), Hubaux (1956), and others. There are three types of ilmenite deposits: (1) ilmenite, (2) vanadium-bearing magnetite-ilmenite, and (3) apatite-bearing magnetite-ilmenite. Production of ilmenite has come only from Type 1 deposits (Storgangen and Tellnes), except for a small amount produced from a Type 2 deposit (Rodsand), as a byproduct from magnetite production. These three commercial deposits all occur in the Egersund anorthosite in southwestern Norway.

Finland: *Otanmäki Deposit*—The ilmenite-magnetite deposit at Otanmäki is located almost at the geographical center of Finland. The Otanmäki deposit and a neighboring deposit at Vuorokas were discovered in 1938 as a result of magnetic surveys by Veikko Okko of the Geological Survey of Finland (Harki, et al., 1956).

Rock Deposits—Potential Sources

Brazil: *Tapira and Salitre Titanium Deposits*—These deposits are unique in that their major titanium mineral is the anatase (or octahedrite) polymorph of TiO₂, rather than rutile or ilmenite. The deposits occur in an alkaline pipe, 6 km (4 miles) in diameter, about 48 km (30 miles) southeast of Araxá in Minas Gerais. According to the National Department of Mineral Production, proved and indicated reserves contain 108 million st of TiO₂ (Anon., 1980a). In places, anatase may make up as much as 70% of the ore. In preliminary tests concentrates containing up to 86% TiO₂ were produced with very low chromium and vanadium content, said to be suitable for producing TiO₂ pigments by the chloride process. These concentrates have some solubility in sulfuric acid (Anon., 1972).

Through 1979, about 12 million tons of anatase-bearing ore had been mined and stock-piled in conjunction with phosphate production.

Mexico: *Pluma Hidalgo Deposit, Oaxaca*—The Pluma Hidalgo Deposit occurs in an area known for some time to have scattered occurrences of rutile, and is located about 125 km (78 miles) south of the City of Oaxaca, the state capital. Starting in 1953, Republic Steel Corp. carried out an extensive program of exploration, but did not find high grade ore bodies large enough to justify a mining operation. In 1957, when the price of rutile dropped substantially, the project was discontinued.

Paulson (1964) described the dominant country rock as a quartz feldspar gneiss, or granulite, which may be classed as an anorthosite by analogy with the anorthosite associated with the similar Virginia titanium deposits. The common mineral association in ore zones is ilmenite, rutile, and apatite in a green rock that is mostly chlorite.

Sand Deposits—Principal Producing Countries

United States: All commercially important titanium mineral sand deposits in the United States are within the Atlantic and Gulf Coastal Plain geologic provinces. States which have established or potentially exploitable heavy-mineral-bearing sands are Florida, Georgia, New Jersey, and Tennessee.

Concentrations of heavy minerals in the coastal areas of the southeast are related to both recent and ancient marine shorelines, the latter of Pleistocene age. Up to seven old shorelines have been identified by different investigators (Cooke, 1941, 1945; Flint, 1940, 1942, 1947; MacNeil, 1949; Parker and Cooke, 1944), but the most widely recognized are: (1) Okefenokee, 46 m (150 ft), (2) Wicomico, 31 m (100 ft), (3) Pamlico, 8 to 11 m (25-35 ft), and (4) Silver Bluff, 2 to 3 m (8-10 ft) above sea level. All are regarded as lines of farthest marine transgression during interglacial and postglacial periods, and all have produced commercial heavy mineral deposits. Mining began where black sands were exposed on modern beaches, and when these deposits were exhausted, operations moved inland to the larger and harder-to-find deposits of the older elevated strands. Florida

has three heavy mineral mines operating with possibilities for more in the future; Georgia's only deposit exploited to date recently has been worked out but, again, other occurrences of possibly economic size and grade are known.

In central New Jersey two operations have recovered titanium minerals and byproducts from Pliocene sands of the Cohansey formation, about 24 km (15 miles) inland from the present shore.

The host for heavy mineral deposits in western Tennessee which have been considered for mining is the Cretaceous McNairy sand out-cropping within the Mississippi embayment of the Gulf Coastal Plain. Past, present, and possible future ore bodies in each of the three areas of occurrence are considered in turn below.

Florida and Georgia—Storm-line concentrations of heavy minerals in modern beach sands have been mined for ilmenite at two locations on Florida's eastern beaches. Mining began at Pablo Beach near Ponta Vedra in 1916 (Martens, 1928), and Riz Mineral exploited a deposit on the ocean front near Vero Beach in later years. Similar modern beach, bar, and barrier island black sands are found on the northeast and west coasts of the peninsula and along the shore of the western panhandle. The ratios among species in heavy mineral suites in the western Florida occurrences are different from those in eastern deposits, probably because of dissimilar ultimate sources on opposite sides of the southern Appalachian Mountains. The potential ore reserves in the known near-shore concentrations are small, with the possible exception of Amelia Island in extreme northeastern Florida, Cumberland Island just to the north in Georgia, and several others of the Sea Island chain formed as barrier islands during the development of the Silver Bluff shoreline. Land values in the islands have increased because of their growing popularity as resort areas over approximately three decades since the heavy mineral deposits were first drilled, so that mining may not be economically competitive with tourism and recreation.

Elevated sand bars were mined by Riz Mineral south of Vero Beach and by Humphreys Gold Corp., on behalf of Titanium Alloy Manufacturing Co., in a Pamlico shoreline feature just west of Jacksonville Beach. These deposits are now mined out.

Just south of the St. Marys River, which forms Florida's northern boundary, and northeast of the community of Yulee, ITT-Rayonier owns land containing an unmined heavy mineral deposit which has been drilled by several organizations, most recently by Pennsylvania Glass Sand Corp., the ITT-Rayonier subsidiary. Ore grade lenses form low north-south ridges, interspersed with shallow swamps, and rest on clay and shell beds. The Yulee deposit is also a Pamlico shoreline development.

In Georgia other black sand concentrations, all related to the Pamlico shoreline, are located north and south of Brunswick and south of Savannah. Potential ore reserves are modest in all known cases, as they are at Yulee, but exploitation might be possible if the same mining equipment could be used at several deposits sequentially, and if a heavy mineral concentrate could be economically transported to a central separating plant.

TRAIL RIDGE, FL. The broad sand ridge that extends from the southern parts of Clay and Bradford counties in north-central peninsular Florida for 201 km (125 miles) northward into southeastern Georgia, called Trail Ridge, is thought to have formed by one or more of several processes in late Miocene or Pliocene time.

Du Pont's Trail Ridge ore body occupies the southern 29 km (18 miles) of the western part of the feature, and is from 2 to 3 km (1 to 2 miles) wide. The base of the ore body is at an elevation of 44 m (145 ft) to more than 61 m (200 ft) above sea level, and the average thickness is 11 m (35 ft). It overlaps barren coarse sand on the east. An indurated layer of concentrated organic material comprised of decomposed remnants of roots, branches, and trunks of trees underlies the central portion, and the western margin lies on pre-Pleistocene clayey sand in many places (Grogan, et al., 1964).

The heavy minerals are thinly layered and disseminated in brown, oxidized, cross-bedded sand. In random lenticular areas at various depths organic materials and clayey minerals cement the sand grains to form a poorly consolidated sandstone locally called "hardpan." The average grade in heavy minerals is low, only about 4%, but there are about 45% high-TiO₂ minerals in the heavy mineral suite (Pirkle and Yoho, 1970).

The titanium ore minerals are altered ilmenite, leucoxene, and a very little rutile. Staurolite, zircon, tourmaline, spinel, kyanite, sillimanite, monazite, corundum, and topaz are also present. Authigenic pyrite occurs in small amounts associated with present-day swamps. The absence of monazite, garnet, and epidote, which are common in the underlying formations and in other southeastern heavy mineral deposits, implies different source rocks and a different age for the Trail Ridge minerals. The absence of these three minerals makes the separation and marketing of staurolite possible.

Alteration of the titanium minerals by oxidation and leaching of iron has been extensive.

GREEN COVE SPRINGS, FL. About 32 km (20 miles) east-southeast of the south end of Trail Ridge an ilmenite-leucoxene-zircon-monzite heavy mineral deposit was mined by Titanium Enterprises, a joint venture of American Cyanamid and Union Camp Corp., until 1978 when mining ceased for economic reasons. In 1980 the property was purchased and mining resumed by Associated Minerals (U.S.A.) Ltd., Inc., a subsidiary of the Australian firm, Associated Minerals Consolidated Ltd. The ore body is near the eastern margin of the Duval Upland, which is thought to be a regressive beach ridge plain, and is probably related to an ancient shoreline at an elevation of 27 to 31 m (90 to 100 ft) above present sea level or to the Wicomico shoreline of MacNeil (1949).

The ore zone at Green Cove Springs is 16 to 19 km (10 to 12 miles) long, 1 km (¾ mile) wide, and it averages about 6 m (20 ft) thick. The heavy minerals comprise 3 or 4% of loose to slightly consolidated quartz sands which are underlain by subgrade quartz sands, by brown and gray sands containing some clay, by shell beds, and finally, at a depth of 31 m (100 ft) or more below surface, by limestone and dolomite.

The grain size of both quartz and heavy minerals is smaller than at Trail Ridge. Also, the heavy mineral suite, containing a significant percentage of monazite together with minor amounts of epidote and garnet, is different. It has been suggested (Pirkle, et al., 1974) that while the Trail Ridge concentration of heavy minerals was derived from the Northern Highlands of the northwestern part of peninsular Florida, the Green Cove Springs deposit was formed from the sands of the Duval Upland to the east.

BOULOUGNE, FL. Humphreys Mining Co. from 1974 to 1979 mined a heavy mineral deposit about 3 km (2 miles) south of the town of Boulougne on the St. Marys River,

which forms the boundary between extreme northern Florida and Georgia. It was located near the eastern edge of the Duval Upland at an elevation above sea level the same as that at Green Cove Springs, and had similarly fine sands containing monazite, garnet, and epidote. The two deposits probably had a common genesis.

FOLKSTON, GA. Du Pont, in a program of systematic examination of elevated bars and old high level shorelines along the Atlantic Coast, discovered the Folkston heavy mineral deposit in 1952. It was situated in a flat, broad elevated area a few miles north of the Boulougne, FL, ore occurrence and the two may at one time have been one, later cut by the St. Marys River. The flat area is better described as a marine terrace rather than a sand bar or old shoreline, as it is up to 6 km (4 miles) wide and over 32 km (20 miles) long. The zone in which commercial deposits of heavy minerals were found, 8 km (5 miles) east of Trail Ridge, is not geomorphically different from the remainder of the terrace. It is a relatively thin layer of sand resting on clay. Three lenses were outlined in development drilling: the Main Area, the West Extension, and the North Extension. Each of the lenses was bounded by swamps, underlain by barren sand and clay, which were probably original depressions rather than erosion channels. Humphreys Mining Co. completed mining of the Main Area for Du Pont in 1974 and moved mining and primary concentrating equipment to Boulougne, FL.

New Jersey—The New Jersey Geological Survey, in an exploration program which grew out of observations of minor titanium mineral concentrations during investigation of monazite placers as sources of radioactive materials, identified the upper Tertiary sediments in the northern part of New Jersey's Coastal Plain as an ilmenite province in 1956 (Markewicz, 1969). The main heavy mineral formations were found to be the Miocene Kirkwood marine micaceous sand, silt, and clay, the Pliocene (?) Cohansey fluvial poorly sorted quartz sand, and the Pleistocene Cape May sands and gravels derived from the Kirkwood and Cohansey and from sediments farther inland. The Cohansey formation, which contains the greatest concentrations among these three, is ilmenite-rich in the northern third of its extent in New Jersey, in the vicinity of Lakehurst, about 48 km (30 miles) southeast of Trenton. Exploratory drilling by private companies resulted in the discovery of four ore bodies, and two heavy mineral mines were established.

LAKEHURST, NJ. The deposit of Glidden Pigments Group of SCM Corp. was located at Legler, about 3 km (2 miles) due north of Lakehurst, and was mined from 1962 to 1978. A mantle of Pensauken sand and gravel from 0.3 to 3.0 m (1 to 10 ft) thick overlay the Cohansey ore body, which was from 6 m (20 ft) to more than 12 m (40 ft) thick, with the average being 8 m (25 ft). A barren red sandstone 6 to 12 m (20 to 40 ft) thick underlay the ore, and beneath it was a zone in the Kirkwood formation, more than 12 m (40 ft) thick in places, averaging 4.5% heavy minerals. Only the Cohansey ore was mined.

MANCHESTER MINE. The Manchester mine of Asarco, Inc., also in the Cohansey formation, was about 97 km (60 miles) south of New York City, near Lakehurst, NJ. Geological features are similar to those at the Glidden operation at Lakehurst. Reserves were reported to be 180 million tons of sand averaging about 4% heavy minerals (Anon., 1974a) and 1.95% TiO_2 (Li, 1973). The operation was expected to have a 20- to 22-year life from 1973 when production began, based on a planned initial rate of 155,000 tons and a possible

ultimate rate of 185,000 tpy of ilmenite, averaging 63% TiO_2 . All ilmenite produced was under a sales contract to Du Pont. The mine was closed in March 1982 because of escalating costs and the prospect of a long-term oversupply situation.

Tennessee—A reconnaissance exploration program conducted by Du Pont to investigate reports of surface heavy minerals in 1957-1958 led to discoveries of ore grade occurrences of titanium minerals in the Cretaceous McNairy formation. McNairy is a poorly consolidated, clay-bearing fine-grained sandstone, about 91 m (300 ft) thick, which outcrops in a north-south belt just west of Kentucky Lake. The dip is very gentle to the west. Heavy minerals, including ilmenite, leucoxene, rutile, zircon, monazite, and minor amounts of kyanite, staurolite, tourmaline, and xenotime, are concentrated in the lower portion of the McNairy above the underlying Coon Creek formation. The ilmenite is somewhat altered, and concentrates have shown an average of about 62% TiO_2 .

Ethyl Corp. and Kerr-McGee carried out exploratory drilling programs during the period 1970-1972, and both companies outlined several ore bodies. Production plans were deferred because of environmental problems and changing markets.

Australia: Australia is the world's most important heavy mineral sand mining country, producing 64% of the rutile mined in 1982, and 38% of the ilmenite.

Heavy mineral concentrations occur widely around the Australian coast, and small black sand deposits have been reported in Tasmania, Victoria, South Australia, and the Northern Territory. Those at Nepean Bay on Kangaroo Island have been mined in the past. In addition to onshore beach-type deposits, offshore occurrences have been discovered and explored in shallow water along portions of the New South Wales-Queensland coasts. In 1982, however, mining was restricted to three areas: (1) the coast of New South Wales and Queensland from Newcastle to Gladstone, (2) near Bunbury, Capel, and Busselton on the west coast of Western Australia south of Perth, and (3) near Eneabba 29 km (18 miles) inland and about 225 km (140 miles) north of Perth.

As elsewhere, the heavy mineral grains were derived from the erosion of granites, intrusives, quartz reefs, and sandstones, and transported to the coast and concentrated by water and wind action. They occur in present-day beaches, fossil beaches, buried strand lines, and coastal dunes, and may be up to nearly 32 km (20 miles) inland as in Western Australia.

Ratios among individuals in Australian heavy mineral suites vary geographically. For example, between Sydney and Newcastle, rutile and zircon comprise about 90% of the concentrates, while farther north in New South Wales the rutile plus zircon content drops to 60 to 70%. Continuing northward, in southern Queensland the ilmenite level increases to about 60% of the heavy minerals. In the area between Busselton and Bunbury in Western Australia ilmenite makes up about 90% of the heavy mineral fraction, and near Eneabba concentrations contain 40 to 60% ilmenite, and about 10% rutile.

There is also a geographical variation in the chemical composition of ilmenite. Along the east coast ilmenite is generally too high in chromium to be suitable as a raw material for pigments manufacture by the sulfate process, and has found only a limited market in the Japanese steel-making industry. The chromium content does, however, decrease from south to north, and the ilmenite is apparently

suitable for upgrading to rutile grade material by some beneficiation processes. In Western Australia ilmenites from the Bunbury-Busselton area average 54 to 57% TiO_2 , while Eneabba ilmenite grades around 61% TiO_2 .

Titanium mineral mining began in eastern Australia in 1934. Ore bodies were modern beach placers containing up to 50% heavy minerals, mostly rutile and zircon. All these high grade deposits have been exhausted over the past 40 years, and the average grade in the east by 1980 was about 3% heavy minerals. The increased cost of working lower grade deposits farther inland has been offset by improved techniques for mining and processing, and some ore bodies containing less than 0.25% TiO_2 as rutile (plus at least as much zircon) are now mined successfully on the east coast. In Western Australian ore bodies titanium minerals must be more highly concentrated because of the relative scarcity of rutile, and although there are wide variations within individual deposits, the average is between 5 and 10% heavy minerals. Mining of heavy mineral sands began in Western Australia in 1956.

The development of the large and important Eneabba ore field began in 1970. Rutile occurs in the heavy mineral suite there with ilmenite and leucoxene, so that with full-scale production commencing in 1974 and 1975, Western Australia became an important source of rutile for the first time.

Eastern Australia—Ore bodies are in ancient beaches and bars in New South Wales and parts of Queensland. On North Stradbroke and Fraser Islands, they are in high coastal dunes.

The opposition of conservationists to sand mining on Fraser Island led to the withdrawal of export licenses for Fraser Island concentrates at the end of 1976, and to restrictions on sand mining in other areas in Queensland and New South Wales.

Western Australia—Heavy mineral concentrations occur in three separate strand lines in the Bunbury-Busselton area: the present beach, the Capel line, and the Yoganup line, with the Yoganup line being oldest and 16 km (10 miles) inland. The TiO_2 content of the titanium mineral fraction of the heavy minerals increases with distance from the present coast.

Longshore drift in the area is southward and westward toward Cape Naturaliste, and it appears that longshore currents acting in the past sorted sands brought to the coast by north-westward-flowing rivers, creating heavy mineral deposits along beaches near their mouths. The existence of the old Yoganup and Capel lines indicates two past episodes of shoreline standstill.

Commercial concentrates of ilmenite, leucoxene, zircon, and monazite are produced from this region of Western Australia.

Exploration northward toward Perth and beyond resulted in the discovery of heavy mineral occurrences in old strand lines at Boyanup, Waroona, Bull's Brook, and Gin Gin. Rutile appears significantly in the heavy mineral suites at Bull's Brook and Gin Gin. The ilmenite is reported to be high in chromium content and it could be more suitable as a raw material for beneficiation than for direct sale.

ENEABBA. It was suggested by Lissiman and Oxenford (1973) that the heavy mineral deposits at Eneabba were formed by agencies acting similarly to those which formed the ore bodies in the Bunbury-Busselton area. Rapid erosion of a Mesozoic sedimentary rock high-land contributed sand to a westward-flowing stream which emptied into a bay partially protected on the southwest from south-to-north longshore currents by a headland. Longshore drift produced countercurrents within the bay which concentrated black

sands on the beaches south of the mouth of the stream. There are several distinct strand lines marked by north-trending bands of high heavy mineral concentration at the bottom of the ore zone, and they are thought to have been formed during relatively brief periods of sea level standstill. The strand lines are at successively lower levels from east to west. The geologic history of the ore field is made complex by evidence of reworking of the higher strand lines by waves which must have been associated with a sea which rose again, perhaps repeatedly, and by wind which created disseminated heavy mineral sands between and over the strand line deposits. Ore bodies in the northern portion of the district, which is about 16 km (10 miles) long and over 2 km (1½ miles) wide, are thought to have been formed by wind concentration of heavy minerals from black sand dunes then exposed in areas to the south.

Total reserves of the Eneabba district are in excess of 20 million tons of heavy minerals. Rutile, ilmenite, leucoxene, zircon, and monazite are present in variable proportions from one area to another, but the average ratios may be 1:5:0.2:2:0.2, respectively.

KING ISLAND. Beach placers containing heavy minerals are located along the central part of the east coast from Naracoopa some 11 km (7 miles) along Sea Elephant Bay north to Cowper Point. The heavy mineral content is high, up to about 60%. Rutile and zircon occur in about equal proportions. Accessory minerals are leucoxene, ilmenite, magnetite, garnet, and cassiterite.

China: Coastal sand deposits in Guandong and Guangxi provinces contain ilmenite, zircon, and other heavy minerals (Brady, 1981).

India: At one time India was a leading producer of ilmenite from the state of Kerala (formerly Travancore-Cochin). The beach sands were mined in the Manavalakurichi (M.K.) area and later the Quilon deposit of ilmenite near Chavra was put into production. These deposits supplied the bulk of the titanium ore used by the US prior to World War II.

The two deposits have more differences than similarities. The ilmenite in the M.K. deposit analysed only 54% TiO_2 and the sand was rich in garnet and monazite. The ilmenite in the Quilon deposit analyzes about 60% TiO_2 . The sand carried almost no garnet and is high in monazite in only two places.

Malaysia: Substantial tonnages of ilmenite are produced in Malaysia as a byproduct of tin mining either as rough concentrates in mills using magnetic separation techniques or in the form of *Amang*, a crude mixture of heavy minerals which has to be further treated to recover the ilmenite content. The main centers of production are at Perak and Ipoh. The deposits are alluvial in nature.

Sierra Leone: A deposit along the Sherbro River was originally developed as a joint venture of Pittsburgh Plate Glass Co. and British Titan Products. Although relatively high grade ($\pm 1.5\%$ TiO_2) the sands were extremely fine and disseminated in lumpy lateritic clay. Reserves are estimated to be between 3 and 30 million tons of contained rutile. The ore problems plus mechanical and political difficulties caused Sherbro Minerals to shut down in 1971 after only two years of operation.

Bethlehem Steel acquired 85% ownership of the property in 1976 (15% Nord Resources) and conducted an extensive prospecting and geological investigation that extended into 1977, finding higher grade deposits ($\pm 2.5\%$ TiO_2) than that mined by Sherbro. Improvements were made in both the wet and dry flowsheets and as of 1981 the operation now called

Sierra Rutile Limited was approaching specifications and design capacity of 110,000 stpy.

Rutile grades are highest in the topsoil, averaging 2.5% TiO_2 , and in the basal sands and gravels, with up to 3.0% TiO_2 . The average grade of the Mogbwemo deposit where Sierra Rutile began mining in 1979 is over 2.0% TiO_2 (Anon., 1981).

South Africa, Republic of: Shipments of rutile and zircon were started in 1977 from the Richards Bay mineral sands operation in Natal. Richards Bay Minerals manages the combined affairs of Tisand Pty. Ltd. and Richards Bay Iron and Titanium Pty. Ltd., the companies responsible for the operation of the mine and the smelter, respectively. A high- TiO_2 , low-magnesium-plus-calcium slag (RB slag) containing 85% TiO_2 has been produced from ilmenite since 1978, and is reportedly suitable for use in either the sulfate or chloride titanium dioxide pigment processes. Since 1980, production rates have approached planned annual capacities of 440,000 tons of RB slag, 220,000 tons of low-manganese iron, 53,000 tons of rutile, and 110,000 tons of zircon. Proven reserves were estimated at 770 million tons grading 5% ilmenite, 0.3% rutile, and 0.65% zircon. Principal shareholders at the end of 1980 were QIT-Fer et Titane, Inc. (32%), General Mining Union Corp. (30%), and the Industrial Development Corp. of South Africa Ltd. (16%).

Sri Lanka: Sri Lanka contains extensive beach deposits of titanium-bearing sands at Pulmoddai, Tirukkivil, Kelani River, Kalu River, Modoragam River, Kudremalai Point, Negombo, and Induruwa.

The Pulmoddai area contains 5.6 million st of titaniferous material with 2.451 million st of contained TiO_2 . The deposit extends for a distance of 7 km (4½ miles), has a maximum width of about 91 m (300 ft), and a thickness of about 2.4 m (8 ft). There is no overburden. The deposit contains about 80% ilmenite and rutile.

The separation of rutile has been adversely affected by the presence of excessive amounts of residual ilmenite and quartz in the tailings. The separation of zircon has been hampered by inadequate water and insufficient wet tabling equipment to handle the extremely fine-grained Pulmoddai ore.

Sand Deposits—Potential Sources

Brazil: Brazilian deposits of heavy minerals on ocean beaches occur in a zone about 161 km (100 miles) long, extending north from the northeast corner of the state of Rio de Janeiro up into the state of Espirito Santo as far north as the Rio Doce. There is also a zone in southern Bahia. Deposits are known to exist near Natal in the state of Rio Grande do Norte.

Egypt: Rich deposits of black sands occur along the northern beaches of the Nile Delta for about 241 km (150 miles). There are two types: one is dark in color and contains about 70 to 90% heavy minerals and a second which is grayish-yellow to dark gray and contains about 40% heavy minerals. The deposits cover areas 10 km (6 miles) long and a few meters (yards) wide and up to 0.5 m (1½ ft) in thickness.

New Zealand: Ilmenite and associated heavy minerals are found in New Zealand on the west coast of South Island from Jackson Bay to Karamea and on the west coast of North Island at the mouth of Waikato River, Muriwai, and at Manukan Heads. Total reserves near Westport are estimated to be between 17 to 31 million tons. Tests of the sand from Westport indicate the titanium content of the ilmenite averages about 47%

Approximately one billion tons of sand are available between Karamea and Jackson Bay from which ilmenite could be recovered. These deposits on the west coast of South Island are believed to be one of the world's major reserves of low chromium ilmenite.

South Africa: Ilmenite-bearing sands occur in scattered deposits along the east coast of the Republic of South Africa from the area of East London to the Mozambique border and northward. Ilmenite sands also occur along the west coast particularly in the Vannhyrodorp district.

Titanium minerals are found on the east coast in three types of deposits: (1) older red and brown coastal sands, (2) recent dunes and beach sands, and (3) alluvium in coastal lagoons.

Older red and brown coastal sands occur in a belt of undulating fixed dunes which is roughly parallel to the coast. The belt ranges from a few meters (yards) to 6 km (4 miles) or more in width. Some dunes are as much as 152 m (500 ft) high but the average height is much less.

Ilmenite concentrates occur in the alluvium in coastal lagoons, i.e., lagoon sands and in the bars at river mouths.

On the west coast, ilmenite-bearing sands exist in the Vannhyrodorp District between Strandfontein and the mouth of the Zout River. One deposit, a recent dune, skirts the coast for 6 km (4 miles) and another on the Geelwae Karoo is found in a narrow modern beach about 8 km (5 miles) long. The sands are unconsolidated and fine to medium grained.

Titaniferous sandstone containing up to about 50% ilmenite with lesser amounts of rutile and zircon occur in the Ecce series of the Karoo system. They outcrop in several areas, principally near Bothaville about 483 km (300 miles) from the east coast in the Orange Free State. Total reserves are estimated at 85 million tons of material, some of which might be recovered with future technological improvements.

Uruguay: Black sands are found northeast of Montevideo at Agua Dulces, in the state of Rocha. The sands extend along the coast for a distance of 11 km (7 miles) with an average depth of 5.5 m (18 ft). Reserves are estimated at 3.3 million tons of heavy minerals, with an average 2.5% heavy mineral concentrate.

China: Titanium sand deposits are known at Luanping and Chente, and the coast of Jiangsu province.

Korea: Resources of 2,535,000 tons with 507,000 tons of contained TiO_2 have been identified.

Mozambique: Rutile and ilmenite are known to exist on the coastal beaches of Mozambique north of 16°30' latitude and near Vila Luisa, about 40 km north of Lourenco Marques.

USSR: Deposits have been identified along the Black Sea, Aldan River, Boludka River, Pit River in Siberia, Sylvestra River, Chusovaya River, and Vizhai River in the Urals.

EXPLORATION AND EVALUATION

Hardrock Ilmenite Deposits

Hardrock ilmenite deposits, because of their inherent magnetic properties, are readily amenable to the application of aero and ground magnetic geophysical surveys. With few exceptions, these deposits respond to such an application by reflecting abnormally positive magnetic intensities (gammas).

Examples can be cited, however, where negative magnetic anomalies are associated with such deposits. In such cases, the ore occurs either as a titaniferous-hematite concentration or a titaniferous-magnetite occurrence when the titanium

content is greater than the iron content. Theoretically, it would seem possible that a commercial deposit may exist where no magnetic response would be obtained. Such a deposit has not yet been found.

Once such anomalies are mapped, further exploration may take place in the form of detailed surface geological observations and ultimate drilling to first test the anomalies and hopefully to delineate a viable ilmenite deposit.

MacIntyre Development: The original discovery of magnetite-ilmenite deposits at MacIntyre Development, Tahawus, NY, was made from surface outcrops. Extension of these outcrop locations has been made through use of geophysical methods and diamond drilling.

Geophysical—Since the ore is magnetic, the geophysical methods used have been for the purpose of outlining magnetic anomalies. Early work was by dip needle readings over a grid pattern extending outward from surface outcrops. With the advent of the aerial magnetometer the entire property was flown. This produced anomalies well beyond any previous work extending to areas of deep overburden and underlake area.

Aerial work was followed with detailed ground magnetometer readings taken on 15-m (50-ft) spacings along section lines 30 m (100 ft) apart. This served to guide the location of diamond drill holes for exploratory drilling on one or two sections with drill holes spaced 122 m (400 ft) apart on section.

The initial ground magnetometer work on any anomaly is a section across the center of the anomaly at right angles to the long axis indicated from aerial work. The magnitude and gradient of the ground anomaly compared to the magnitude and gradient of the aerial anomaly, along the same section, gives an indication of depth and configuration of the source of the anomaly.

Drilling—If initial diamond drilling indicates an economic deposit, development drilling proceeds on a set grid pattern of 61 or 91 m (200 or 300 ft). Intermediate holes are drilled where necessary to fill in major gaps in geologic interpretation of structure, or ore continuations.

Core Sampling—Drill cores are visually logged and split for chemical assay. In ore areas, samples are taken of the entire core and composited in 1.5-m (5-ft) intervals for assay. In waste areas samples may be taken every 1.5 m (5 ft) and composited for a maximum of 8 m (25 ft) of core. Routine assaying is done to determine TiO_2 and total iron content. Based upon past experience, the nominal cut-off for ore is 13.5% TiO_2 .

Mill Testing—Metallurgical laboratory work is done using core assay rejects to determine milling characteristics. Concentrates from the laboratory work are used for testing end use performance. Complete analyses are run on concentrates to determine presence and quantity of detrimental elements.

Tellnes Deposit, Norway: The Tellnes ilmenite deposit near Hauge-I-Dalane in Norway was discovered in 1954 as a result of an airborne magnetometer survey carried out for Titania A/S, with the object of locating new sources of ilmenite to provide an alternative to developing additional underground ore at Storgangen. Anomalies were also found at four other locations, so that ground geological study and diamond drilling had to be done at all of these sites to be certain that the best deposit was selected for development. A total of 10,058 m (33,000 ft) of drill holes was completed in 1956, and showed the total amount of ore in the Tellnes deposit to be about 300 million tons, averaging 18% TiO_2 (Brun, 1957; Anon., 1978a).

Allard Lake (Lac Tio) Deposit, Quebec: Preliminary investigation of the original ilmenite discoveries at Allard Lake (Hammond, 1949), indicated that all of these were too small to be of commercial importance. A detailed exploration program was carried out in 1946 to more thoroughly explore the area of 647 km^2 (250 square miles) where ilmenite had been found along certain of the lakeshores.

Otanmäki Deposit: The Otanmäki ilmenite-magnetite deposit and a neighboring deposit at Vuorokas were discovered in 1938 as a result of magnetic surveys by the Geological Survey of Finland (Harki, et al., 1956).

Sand Deposits

Exploration: There are only a few large areas of the world where the granite-clan rocks and high-grade metamorphic gneisses which are likely to contain ilmenite (not titaniferous-magnetite) and rutile are close enough to continental margins to have contributed their erosion products to the sediments of coastal plains. Well-sorted sands are much more likely hosts than unsorted sands. These are the areas on which exploration efforts should be focused. Since the alteration of ilmenite to remove iron is aided by humic acid developed by the decomposition of organic material near the water table in hot and humid climates, it follows that the highest TiO_2 ilmenites are more likely to be found in the tropical and temperate regions of the world.

Titanium minerals are dark-colored and their concentration, as in black beach sands, tends to be fairly readily noticeable against the light brown or white quartz. Many sand ore bodies, therefore, have been discovered through surface observation of high-grade placer zones formed on beaches and along the courses of streams, and by following their traces into the larger, lower grade concentrations which constitute economic ore bodies.

There are areas in which potential heavy mineral concentrations in ancient beach sands may be masked by younger sand, gravel, or soil. Exploration under these circumstances then involves interpretation of geomorphic and subsurface geologic data to define areas which could have been beaches or dunes in the past, and then drilling to obtain samples.

Field Techniques—In areas where heavy mineral concentrations are suspected but where the concentration level is difficult to estimate because of dissemination, as in dunes, hand panning of samples is an excellent method of rapidly producing a clean concentrate. A hand magnet gives a quick identification between ilmenite and magnetite or titaniferous-magnetite. The presence of potentially valuable byproduct zircon, monazite, kyanite-sillimanite, etc., can be determined with a hand lens. A Geiger counter or scintillometer also helps in identifying radioactive minerals such as monazite and zircon. Wind and current action can develop very high-grade layers of heavy minerals on the surface which have no economic significance; thus samples for panning and examination should be taken from the maximum convenient depth. Often an idea of the vertical distribution of heavy minerals can be gained from observation of wave-cut cliffs in sands behind the beaches, cutbanks in stream margins, road cuts, construction excavations, and material encountered in sinking or drilling wells. Dark, heavy minerals may even be observed in the sand brought to surface by burrowing insects and small animals.

Hand augering with a two-man crew is possible to a depth of 6 m (20 ft) or more with a jointed auger stem and is reasonably rapid and inexpensive. Some heavy-mineral bearing sands contain so much clay that they are difficult to hand auger and a mechanical auger mounted on a light off-the-

road vehicle (like a post-hole digger) is preferable. The samples so obtained are not precise because of the contamination of the hole by sand falling into it. The hole cannot be advanced nor reliable samples obtained below the water table when the material is free-flowing and easily disturbed by the auger.

Drilling—For the first phase of development, drilling equipment should have a depth capability of at least 15 m (50 ft) and preferably 30.5 m (100 ft). The selection of the type of drill will depend upon the "stiffness" of the ground as influenced by clay, hardpan, caliche, indurated and iron-oxide cemented layers; the presence of roots, stumps, and other organic material; as well as upon the elevation of the water table.

The truck-mounted jet drill is a popular exploration and development tool of the southeast US. One-inch flush-jointed steel pipe, with a chisel lower end or bit and perforations near the bit to permit water to jet forward and downward, is attached to a hammer of about 136 kg (300 lb) which is activated in 0.3-m (1-ft) strokes by a hand-held rope about a capstan winch. Water is supplied to the bit by a swivel connection above the hammer and by a duct through it. As the hammer rises, falls, and turns, it causes the bit to chop and churn into the ground and drives a 59-mm (2-in.) casing downward. The water pipe is within the 59-mm (2-in.) casing. The bit of the water pipe is about 25.4-mm (1-in.) or less ahead of the casing when casing and hammer are in contact. The sand sample is flushed out of the hole continuously by water rising in the annulus between water pipe and casing, and is collected at the surface in vessels or tubs. A jet drill under favorable conditions with short moves between holes can drill about 61 m/d (200 fpd) of hole. Its disadvantages lie in its inability to penetrate very hard layers, and the casing can stick in tenacious clay.

The auger-within-an-auger type of drill has good depth and penetration capabilities, particularly in the less free-flowing sands. The internal auger is advanced about 1.5 m (5 ft) to collect a sample on its flights, then the external auger is put down to the same depth to form a casing, and the internal auger is withdrawn for sample collection. There is some possibility of particularly fluid sands below the water table invading the casing when the internal auger is raised.

In Australia extremely light, gasoline-powered augers, portable and operable by two-man crews, have been developed and used for rapid, low-cost depth investigations. They are particularly successful in high, clean dunes.

A truck-mounted rotary drill driven by rapid strokes of a hydraulic hammer is also very useful. The drill string is a double pipe, and compressed air forced down the inner pipe returns the sample in the annulus between the drill-pipe and casing. A drag bit with hardened cutting edges may be used.

It is important in all types of machine drilling to avoid contamination of samples by material originating higher in the walls of the hole. The hole and casing should be flushed free of loose sand after collecting each sample, and before the bit is advanced farther.

The nature of the sand and other materials penetrated by the drill is usually logged by a geologist, who makes a rough estimate of heavy mineral content and variation by panning a small portion of each sample.

Depending on hole diameter, a 0.9 or 1.5-m (3- or 5-ft) sample may be too large for laboratory requirements. If so, a simple heavy duty riffle may be used to reduce the weight to about 2 kg (5 lb). The bulk of the samples may then be bagged or drummed and left at the hole site for future reference.

Geophysical Techniques—Some titanium mineral ore bodies contain sufficient iron to be detectable by magnetometers in ground or airborne surveys, but many are too dilute and shallow to respond.

If monazite or radioactive zircon is present, low-level radiometric surveys may help in exploration. Scintillometers and Geiger counters are sometimes useful on the ground to define horizontal limits of ore and to detect internal variations in heavy mineral concentrations close to the surface.

The problem of downward contamination during drilling can lead to a misrepresentation of the total depth of ore because the heavy minerals, being higher in specific gravity, are hardest to remove by flushing with air or water and may be reported even when the hole has been advanced into barren underlying sand. A scintillometer probe with a surface recording instrument can show a sudden decrease in radioactivity from the walls of the hole at the true bottom of the ore. Radiometric surveying of all or at least some of the holes drilled during development of an ore body is a highly desirable check on the fidelity of drilling and sampling.

Evaluation of Deposits: An economic titanium mineral deposit must have reserves large enough to support depreciation over a period of at least 10 to 20 or more years. The capital investment in 1980 was in the range of \$75 to \$80 million in the US for a mine and mill plant with an output of 100 to 200 thousand stpy of ilmenite (or equivalent rutile) with given "normal" geologic parameters. Significant contributions can be made by zircon and other byproducts. Another general rule is that a new and separate ore body, if its production is to be all ilmenite which cannot be treated in an existing mill, should have a minimum reserve of about 1 million tons of recoverable TiO_2 in the titanium minerals. Small, high-grade concentrations are uneconomic under the present conditions.

The definition of economic reserves depends, of course, upon many factors, among them:

- 1) Cost of mining and milling, as influenced by depth of overburden (if any); cost of surface and mineral rights; and availability of water, power, labor, and transportation facilities for bulk shipments.
- 2) Recoverability in mining and milling.
- 3) Cost of treatment and disposal of waste slimes.
- 4) Cost of waste water treatment and land reclamation.
- 5) Distance to markets and cost of transport.
- 6) Ability of markets to absorb the type of titanium minerals to be produced, and prevailing prices for titanium minerals and byproducts.

26. Vermiculite*

Vermiculite is the name generally applied to the group of hydrated ferromagnesian aluminum silicates that are characterized by the ability to expand when heated. This process, called exfoliation, results in a lightweight product of commercial value. Most uses of vermiculite are for the expanded material. The chief markets are in construction, agriculture, and horticulture, with lesser uses in general industry.

COMPOSITION AND PROPERTIES

Vermiculite, in its natural state, has the characteristic micaceous habit, a perfect basal cleavage which causes splitting into thin laminae that are soft, pliable, and inelastic. The structure of vermiculite is basically that of a talc. The prominent monoclinic crystal faces are often marked by lines at 60° and 120°. Hardness varies from 1.5 to 2 or more; specific gravities are between 2.1 and 2.8; color varies from almost clear to amber, bronze, brown, green, or black. Vermiculite feels like talc, especially when wet.

Although much research has been performed on the chemical and structural composition, there is not yet complete agreement on the exact formula. This is to be expected when different workers have examined the many different varieties. Vermiculite is not considered to be a single mineral species but a family of related minerals. The structural formula for a trioctahedral vermiculite may be written:

Hydrobiotite also occurs with vermiculite and is usually considered a vermiculite for commercial uses.

When heated quickly to elevated temperatures, vermiculite expands by exfoliating at right angles to the cleavage into wormlike particles. The name vermiculite is derived from the Latin *vermiculare*, to breed worms. This characteristic of expansion is the result of the mechanical separation of the layers by the rapid conversion of contained water to steam. The decrease in bulk density of commercial grades is usually approximately 10 times, from 801 to 80 kg/m² (50 to 5 pcf), but varies depending on the quality, size, and furnace efficiency. Individual flakes may expand up to 30 times. Vermiculite may also be expanded by soaking in chemicals such as hydrogen peroxide, weak acids, and other electrolytes. Color change during expansion is dependent upon the type of vermiculite and furnace conditions. Heating in an oxidizing atmosphere produces a dull gray or tan color, whereas a reducing atmosphere can produce a bronze or gold color.

The expansion of the vermiculite crystal results in large pores being formed between the platelets. Thus, exfoliation makes available a large increase in void volume which is important in the application of vermiculite as a chemical carrier.

Mathieson and Walker (1954) state vermiculite must be regarded as a true clay mineral. The characteristic properties of the mineral, such as high cation exchange capacity, organic complexing ability, and variable interlamellar distance are very similar to those of montmorillonite. The cation exchange capacity of vermiculite is one of the highest of all the clay minerals. The interplatelet space is accessible to penetration

by some electrostatically neutral molecules. Water and glycerine are two common substances whose molecules may be so imbibed.

In the natural state and under normal atmospheric conditions, water occupies the spaces between the silicate layers. The crystal *d*-spacing is near 14.2Å. By differential thermal analysis, it has been determined that the water is released at three temperature ranges. The "unbound water" is released near 149°C (300°F). This water is reversible and comes to equilibrium with the environment. The second water, designated "bound water," is removed at about 260°C (500°F). This is the water necessary for exfoliation. The third water is released at approximately 871°C (1600°F) and is probably hydroxyl. Little of this water is released by commercial exfoliation and when it is, a very noticeable change occurs in the color and physical characteristics of the product.

Vermiculite is closely related to biotite and phlogopite. The essential difference is that the unit cell of vermiculite contains a layer of water and the biotite contains a layer of potassium. Biotite or phlogopite are almost always associated with vermiculite in commercial deposits and are sometimes intermixed within crystals or across a single crystal face. The term *hydrobiotite* has been used for those varieties where the analysis indicates that there is a layered mixture of the two minerals in some definite proportion.

ORIGIN

Detailed investigations have been made of the three largest commercial deposits of vermiculite. According to Boettcher (1966), the Rainy Creek alkaline-ultramafic complex near Libby, MT, represents a composite of successive intrusions of igneous rocks emplaced into the Precambrian metasedimentary rocks. Most of the biotite in the inner body of pyroxenite has been altered to hydrobiotite and vermiculite. From his studies, Boettcher suggests the vermiculite is a product of leaching of the biotite by ground waters, whereas the hydrobiotite may represent a higher temperature alteration product.

Stewart (1949) in his report on the vermiculite deposits at Tigerville, SC, states that hydrothermal activity was necessary in the formation of the high grade deposits only to the extent of furnishing the biotite, which was later altered to vermiculite by meteoric waters. Buie and Stewart (1954) determined the paragenetic sequence as:

Libby (1975) suggests that the potassic ultramafic plutons of the Enoree, SC, vermiculite district probably were intruded into Late Precambrian to Cambrian sedimentary rocks and subsequently were metamorphosed. Studies indicate that both the vermiculite and hydrobiotite form under weathering conditions.

The Palabora deposit in South Africa at Loolekop is located in a carbonatite complex. Both the hydrothermal and weathering theory have been proposed for the formation of the vermiculite. There is a gradation of vermiculite to phlogopite or biotite with increasing depth.

The Palabora carbonatite complex (Dekun, 1965) is about 6.4 × 2.4 km (4 × 1½ miles) in size. The dolomite core is surrounded by a thin inner ring of altered phoscorite (serpentine-apatite-magnetite) and an outer ring of diopside

*Excerpt from Strand, P.R. (revised by Stewart, O.F.), 1983, "Vermiculite," *Industrial Minerals and Rocks*, 5th ed., Vol. 2, S.J. Lefond, ed., AIME, New York, pp. 1375-1381.

pyroxenite. Outward from this is a discontinuous 2.4-km (1½-mile) wide ring of fenitized gneisses. Numerous alvikite and orthoclase veins have been injected into the pyroxenite ring. Serpentine, apatite, and magnetite occur in both inner zones, and a pegmatitic pyroxenite zone occupies the center of the northern ultrabasic ring. Vermiculite occurs only in the ultrabasics, especially close to serpentinized patches. Vermiculite also occurs disseminated with apatite. The principal vermiculite areas are located (1) in the north-central pegmatitic pyroxenite 0.8 km (0.5 mile) from the limit of the carbonatite plug; (2) 1.2 km (0.75 mile) south of the core; and (3) in a zone near the southeastern rim of the pyroxenite.

A vermiculite deposit near Louisa, VA, occurs in a body of basic pyroxenite, about 6.4 to 8 km (4 to 5 miles) in diameter, surrounded by gneisses and granitoid type rocks typical of the Piedmont. The vermiculite occurs in varying flake size but nearly all are less than 10 mesh. The grade of vermiculite varies considerably within a few meters (feet) both laterally and with depth. The vermiculite appears to have been altered from biotite by surface weathering. However, little, if any, geological investigation has been conducted on this deposit.

DISTRIBUTION OF DEPOSITS

Vermiculite occurrences have been reported from many countries of the world. As the mineral has become more widely recognized, new occurrences have been reported. Market conditions, location, size, grade, quality, and economics are some of the factors affecting the commercial value and development of a deposit.

In the United States, vermiculite deposits or occurrences are found in Alabama, Arizona, Arkansas, California, Colorado, Georgia, Idaho, Kansas, Montana, Nevada, New Mexico, North Carolina, Pennsylvania, South Carolina, Texas, Virginia, and Wyoming. Production has been reported from California, Colorado, Georgia, Montana, Nevada, North Carolina, South Carolina, Texas, Virginia, and Wyoming. However, production is reported today only from mines in Montana, South Carolina, and Virginia.

Other countries where deposits have been reported are Argentina, Australia, Brazil, Canada, China, Egypt, Finland, India, Japan, Kenya, Korea, Mexico, Morocco, Pakistan, Zimbabwe, Republic of South Africa, Spain, Tanzania, Uganda, and the USSR. Minor production has been reported from Argentina, Brazil, China, Canada, Egypt, India, Kenya, Korea, Mexico, Spain, and Tanzania. Some vermiculite is produced in the USSR, but quantitative data are not available.

PROSPECTING AND EXPLORATION

In the United States vermiculite deposits of consequence are located in two principal areas: the Piedmont region from Alabama to Pennsylvania and in the Rocky Mountain Range from Montana southward into New Mexico, including the central mineral region of Texas. A few deposits occur in eastern Canada in the Precambrian shield.

Vermiculite deposits usually are covered by vegetation because the minerals are soft and when weathered have a considerable water-holding ability. Outcrops showing vermiculite are rare, but in some areas the mineral can be recognized in road cuts. Outcrops of associated rocks such as biotite, alkalic pyroxenites, and dikes of carbonatites or syenite, generally are more noticeable. In most instances, the only field evidence will be the presence of vermiculite flakes in the soil or in stream beds.

The larger commercial size deposits usually are found associated with ultrabasic rock, commonly pyroxenite. The pyroxenite may be intruded by numerous dikes such as pegmatites, syenites, carbonatites. Numerous veins containing vermiculite are found in ultramafic intrusives such as dunites, peridotites, and pyroxenites, but these do not often represent commercial size deposits.

In a vermiculite-bearing formation, the rock will vary from barren to a high content of vermiculite. The bulk of the material containing vermiculite will fall in the 20 to 30% content range. Drilling or trenching is necessary to prove the presence of ore in economic quantities and grade. Since the preservation of flake size is most important, auger or large rotary hole drilling is necessary with special attention to bit design. Diamond core drilling is most impractical.

The primary requirement of a commercial deposit is that the vermiculite be of acceptable quality. The concentrate must expand to a high degree without decrepitating, and the expanded particles must be strong enough to withstand handling. The biotite or phlogopite content must be low, or occur in such a form that it can be kept from mixing with the mill feed. The deposit predominantly must contain flake size material larger than 65 mesh, as there is little demand for the -65 mesh size.

Another characteristic of a commercial deposit is that the ore body be large enough to be mined with modern earthmoving equipment. Vermiculite production is very energy-intensive, as a high percentage of the commercial cost is for mining, reagentizing, drying, expanding, and transportation.

Deposits are considered to be high grade if their content of +65 mesh vermiculite is over 30%, and uneconomical or at least borderline if the content is 20% or below.

27. Wollastonite

GARY PARKISON

INTRODUCTION

Wollastonite is an industrial mineral which is commonly grouped with other filler-extender minerals such as kaolin, calcium carbonate, and talc. Its consumption pattern and usage depend primarily on its unique physical properties. Wollastonite is the only commercially available white mineral that is wholly acicular with typical length to diameter ratios ranging from 3:1 to 20:1 with an average diameter of 3.5 μm .

Most current production is derived from open-pit mines with the world's two largest producers both located in upstate New York. Reserves associated with currently producing operations are generally quite large and sufficient for many years of production given current consumption. There are a number of deposits on a worldwide basis which could be viable potential producers given current product prices and an expanded market.

MINERALOGY, USES AND SPECIFICATIONS

Wollastonite, or calcium silicate (CaSiO_3), has an ideal composition of 48.3% CaO and 51.7% SiO_2 . Substitution of the calcium by iron, magnesium, and manganese is quite common. It is most commonly white or cream in color, has a hardness of $4\frac{1}{2}$ to 5 on Moh's scale, a specific gravity of 2.8 to 3.0, and has a melting point of about 1540°C . The most diagnostic property of wollastonite is, however, its common appearance as bladed, radiating, crystal masses. The crystals are generally acicular with aspect ratios (length:width) ranging from 3:1 to $>20:1$. Owing to perfect cleavage properties, this acicular habit is preserved in crushed and ground wollastonite. A broader discussion of mineralogy can be found in Andrews (1970).

It is the acicular nature of wollastonite which determines its utility in the marketplace as a functional filler-extender mineral. The acicular nature in conjunction with a relatively low melting temperature have contributed to the use of wollastonite in ceramic tile body and glaze formulations. The use of wollastonite in both architectural and special use paint is due primarily to its white color, acicular nature, and low oil absorption. Plastics applications are currently the largest domestic consumer of wollastonite where its acicularity contributes to the impact and flexural strengths in both thermoplastic and thermosetting resin systems. Other applications are as an asbestos substitute in brake linings, backing material for linoleum flooring, and in marine wall-board. A more in-depth discussion of applications is contained in Power (1986).

Specifications for wollastonite used in the various ceramic applications are ball- or pebble-mill ground material with aspect ratios generally less than 5:1 and particle sizes from -72 to $-44\ \mu\text{m}$ (-200 to -325 mesh). More finely ground material, typically 99% less than $44\ \mu\text{m}$ (-325 mesh), is used in paints. High aspect ratio materials (10:1 to $>20:1$) with particle sizes ranging from -72 to $-36\ \mu\text{m}$ (-200 to -400 mesh), are produced via attrition mills and are typically used for plastics and other applications. Coated or chemically surface-treated wollastonite usage is becoming increasingly popular in high performance plastics applications.

A more thorough description of the uses and specifications for wollastonite can be found in Power (1986), Elewatorski and Roe (1983), and Smith (1981).

Synthetic wollastonite has been produced for some years both in the United States and Europe. These plants are generally not economic relative to the costs of natural wollastonite production but do offer more consistent chemistry and product supply. The synthetic products are produced by mixing finely ground SiO_2 and CaCO_3 in a rotary kiln to produce synthetic wollastonite via the sintering process (Rosner and Kurczyk, 1980). On a worldwide basis the production of synthetic wollastonite does not significantly displace natural wollastonite, with the former being restricted to the low aspect ratio "powder" uses primarily in ceramic and metallurgical applications.

GEOLOGY AND MINING

Formation

Wollastonite is most typically a product of contact and regional metamorphism, although minor amounts have been found associated with carbonatites. In a typical contact metamorphic environment with a granitic magma intruding impure calcareous rocks (i.e., limestone or dolomite), the farthest out metamorphosed zone will be the tremolite zone, where dolomite and quartz will react to form tremolite and calcite. The tremolite zone is succeeded by the zone closer to the intrusion where tremolite and quartz react to form diopside. Adjacent to the intrusion in the highest temperature zone calcite and quartz react to form wollastonite while diopside is stable (Winkler, 1974). The quartz can be introduced from the granitic magma, be mobilized from the surrounding sediments, or present within the host rock itself. Similar paragenetic reactions can also form garnet which is also stable with wollastonite, diopside, and calcite and together comprise a rock type commonly referred to as skarn. Within the skarn zone any unreacted calcite would typically be of sufficiently large grain size as to constitute marble.

The reaction

typically takes place in the higher temperature ranges ($>500^\circ\text{C}$.) of shallow contact metamorphism only where the CO_2 -rich fluid phase is sufficiently dispersed to allow the reaction to proceed (Winkler, 1974). While small amounts of wollastonite are relatively common in contact metamorphic aureoles, the conditions to create sufficiently large deposits to be of commercial interest are quite rare and seemingly would be dependent on appropriate host rock bulk chemistry, chemistry of the igneous intrusive, and associated pressure and temperature. In western North America wollastonite is often found as rims and masses around and between remnant chert horizons in what is now calcite marble (Joeston and Fisher, 1988). This type occurrence is often associated with porphyry copper-related skarn deposits (Einaudi, 1981a,b). Even more specific conditions are required for the generation of highly acicular masses of wollastonite.

Significant Deposits—North America

The two largest producing wollastonite deposits in the world are both located in upstate New York flanking the Adirondack Mountains. Wollastonite is mined by NYCO near the community of Willsboro and by R.T. Vanderbilt some 160 km (100 miles) to the west in the Gouverneur region. The NYCO deposits have been described by Andrews (1970) and de Rudder (1962), and include the Deerhead, Fox Knoll and Lewis deposits. The current open-pit mining operation at the Lewis mine is described by Herod (1984) and involves mining and crushing the ore at the mine site then transporting the ore in trucks some 25 km (15 miles) to a mill at Willsboro. At the mill garnet and diopside are separated from wollastonite via dry magnetic separation following fine crushing. Much of the NYCO production is of high aspect-ratio material. In the area of the deposits Precambrian Grenville marble has been intruded and partly replaced by rocks of anorthositic composition to produce mixed gneisses containing wollastonite with garnet and diopside. At the Lewis deposit, original reserves were estimated at 5.4 Mt (6 million st) grading about 60% wollastonite, 30% garnet, and 10% diopside. The wollastonite-rich zone occurs as a single shallow-dipping sheet some tens of feet thick which is intercalated with thinner wollastonitic and gneissic bands. Total ore reserves held by NYCO in the three properties likely exceed 10 Mt (Elevatorski and Roe, 1983). This figure does not include the recently discovered reserves at the Oak Hill deposit adjacent to the Lewis mine.

The deposit being exploited by R.T. Vanderbilt is similar to that of NYCO but lacks garnet and hence is lower in iron content, which make this wollastonite better suited to ceramic applications (Harben and Bates, 1984). The wollastonite zone is mined by both open-pit and underground methods, is steeply dipping, and contains an estimated 0.9 Mt (1 million st) of ore (Power, 1986). Wollastonite production is of low aspect ratio.

Some 160 km (100 miles) to the northwest of the R.T. Vanderbilt deposit in southeastern Ontario, Canada, is a more recent discovery of wollastonite in a geologic setting similar to that of the New York deposits. Drilling by the Cominco/Platinova joint venture has defined total ore reserves exceeding 0.9 Mt (1 million st) in two separate deposits grading from 39 to 47% wollastonite (Anonymous, 1988).

The only other deposits which have been mined for wollastonite in the United States are in California. A small amount has been mined from a deposit in Kern County where Paleozoic limy sediments have been intruded by Mesozoic granitic rocks where the wollastonite is associated with diopside and garnet (Troxel and Morton, 1962). A larger but unknown amount of wollastonite has been mined from several deposits in the Big and Little Maria Mountains near Blythe in southern California. Wollastonite-bearing rock occurs sporadically throughout a thick succession of Paleozoic siliceous and calcareous sediments. Local pods of high purity massive wollastonite can be traced for up to 600 m (1800 ft) in length (Troxel, 1957). Hoisch (1987) has determined that the wollastonite formed where large volumes of high temperature fluids were channeled along permeable or fractured zones during a Late Cretaceous regional metamorphic event.

Large undeveloped wollastonite deposits are located in both the southern and northern extremes of Death Valley National Monument. The Warm Spring Canyon deposit hosts a lens of almost pure wollastonite some 12 m (35 ft) thick and 250 m (750 ft) long within moderately dipping carbonate rocks (Troxel, 1957). Extensive wollastonite min-

eralization in the Hunter Mountain area has been described by Clark (1980) and Andrews (1970). In this area, wollastonite with lesser amounts of garnet, epidote, and amphiboles have preferentially replaced favorable beds in Paleozoic limestone adjacent to a Cretaceous quartz monzonite intrusion (McAllister, 1965). Most of the wollastonite is quite compact and short-fibered and occurs along a band up to 100 m (300 ft) wide and more than 8 km (5 miles) long. Reserves are thought to exceed 22.5 Mt (25 million st) grading 65 to 85% wollastonite. Other wollastonite occurrences in California have been documented by Murdock and Webb (1966) while occurrences in Arizona, Nevada, and Utah are described by Anthony, et al. (1977) and Andrews (1970).

Some of the largest known wollastonite deposits in the world are found about 65 km (40 miles) northwest of Hermosillo, Sonora, Mexico. The Pilares and San Hector deposits both outcrop prominently in isolated hills rising from the desert pediment. Both areas are underlain by Paleozoic age, thickly interbedded, moderately north-dipping quartzite and calcitic marble in close proximity to Cretaceous granitic rocks. Wollastonite mineralization at grades over 70% and many tens of meters thick can be traced for thousands of meters along strike and alternate with marble zones with from 30 to 40% or less wollastonite. Most of the wollastonite is white or buff colored and found as radiating splays or clusters with individual crystals from 1 to 3 cm in length. Commonly associated with the wollastonite are finer-grained quartz, calcite, diopside, and garnet. Reserves of material grading more than 50% wollastonite at both the Pilares and San Hector deposits exceed 30 Mt (33 million st).

Other wollastonite deposits in Mexico are described by Andrews (1970). The only current wollastonite production in Mexico is by General de Minerals, SA, which operates four small open pit and underground mines in the La Blanca district about 50 km east of Zacatecas (Smith, 1981). Relatively thin and erratic steeply dipping zones grading 50% or less wollastonite are developed in thin-bedded limestone. The gray to white wollastonite is associated with considerable calcite, quartz, garnet, and diopside. The wollastonite zones are within one-half mile of a granitic stock. Hand-cobbing upgrades the run-of-mine ore prior to trucking to a grinding mill located near Zacatecas.

Significant Deposits—Europe and Asia

While wollastonite production from North America dominates the world market, a significant and increasing share of production comes from Europe and Asia, specifically Finland, India, and China. Oy Partek AB produces wollastonite from an open pit at the Lappenranta deposit in southeastern Finland in conjunction with limestone production for cement manufacture (Power, 1986; Harben and Bates, 1984). Wollastonite occurs within an elliptical Archean limestone mass in a zone some 650 m (2000 ft) long by about 50 m (150 ft) wide. The zone is fairly low grade, averaging about 20% wollastonite along with considerable calcite, dolomite, and quartz but no garnet (Andrews, 1970). The deposit is thought to have been formed through contact metamorphism by the enclosing younger granite.

Wollastonite production in India is currently from the Belkapahar deposit in the state of Rajasthan by Wolkem Pvt. Ltd. (Power, 1986). Wollastonite is found within limestone horizons which have been replaced by pyroxenites and gneiss in association with contact metamorphism (Sinha, 1986). After hand sorting, the wollastonite has few impurities and is of high aspect ratio. Reserves are very large and production currently is via open-pit mining.

China has been an intermittent exporter of wollastonite for the last several years. Wollastonite is currently produced from numerous small open pit mines in several northeastern Chinese provinces (Fountain, 1986). Most of the operations are labor intensive and make extensive use of hand-cobbing to produce salable lump ore primarily for domestic use. High-grade wollastonite layers are typically enclosed within calcitic marble and most deposits are associated with iron and copper mines.

The USSR is thought to produce a significant amount of wollastonite from several deposits for domestic consumption only. Kuzwart (1984) describes a deposit in Tadzhikistan which hosts high grade coarse-grained wollastonite within Paleozoic limestones at their contact with syenodiorites. Other deposits in the USSR are described by Andrews (1970). Past producing deposits in Kenya, Namibia, and Sudan are further described by Andrews (1970) and Power (1986). Power (1986) also describes potentially commercial wollastonite deposits in Turkey and Greece. Minor production from New Zealand is reported by Powers (1986) and several occurrences in Australia are briefly summarized by Johns (1986).

EXPLORATION

All commercial wollastonite deposits have been found to be associated with calcareous metamorphic rocks, and most of these deposits are near or along zones of contact with granitic intrusive rocks. Chances are good that wherever granitic rock intrudes a sequence of calcareous sediments, at least a minor amount of wollastonite will be developed. Of importance in determining whether a large amount of wollastonite will result is the pressure and temperature conditions associated with the metamorphic event and the bulk chemistry of the calcareous rock. In this latter regard, a siliceous limestone would be preferred as in most instances an isochemical process for the origin of wollastonite within the host rock is suggested. The specific conditions which lead to the generation of long fiber or high aspect ratio wollastonite vs. short fiber wollastonite both in outcrop and in milled product have not been described.

Potentially helpful information which can be used to focus the search for commercial wollastonite deposits could include published descriptions of skarn or carbonate-hosted base metal deposits, specifically porphyry copper type deposits in addition to descriptions of known wollastonite deposits and occurrences. In this instance, a review of state or province publications on mineral resources and/or systematic reviews of minerals can be most helpful. Once a prospective area is determined or located, on-site investigations should initially be concentrated along or near the contact between the intrusive rock, if present, and favorable calcareous rocks. Particular attention might also be paid to the probable metamorphic zonation with wollastonite closer to the intrusive with diopside and tremolite at increasing distance. In arid environments, wollastonite-rich zones are typically more resistant to weathering than the enclosing rocks while in humid areas the opposite is often the case.

EVALUATION

Evaluation of the commercial significance of a wollastonite occurrence involves a number of physical, chemical, and metallurgical tests in addition to the development of an accurate marketing study. The initial testing should involve the collection of outcrop and/or subsurface samples via core or rotary drilling, chip and channel sampling, trench sampling, etc. Testing should be supported and directed by de-

Table 1. Some Typical Specifications of Commercial Wollastonite

Component		Properties
CaO	46-47%	Brightness (Hunter) 85-95
SiO ₂	49-51%	at - 200 mesh sizes
Fe ₂ O ₃	0.1-1.0%	Aspect ratio 3:1 to > 20:1
Al ₂ O ₃	0.1-1.0%	for high aspect uses
MgO	0.3-2.0%	Oil absorption 20-40
LOI	0.5-2.0%	mg/100 g

tailed geologic mapping to determine the width, length, and attitude of the wollastonite mineralization and its host rock associations. Particular attention should be paid to variations in wollastonite and gangue mineral contents and physical aspects of the wollastonite-rich zone. X-ray diffraction testing and petrographic examinations of representative and select samples should be used to determine modal mineralogy in conjunction with routine X-ray fluorescence analyses for major and minor elements. In many cases, the modal and chemical analyses are correlative and provide a good basis for further grinding and/or beneficiation studies. Grinding of unbeneficiated and beneficiated feed should utilize one of a number of grinding options including a jet and/or attrition mill to maximize aspect ratio. Beneficiation can employ hand-sorting, wet or dry magnetic separation, flotation, or a combination of methods. Products from all testing phases should be reanalyzed for chemistry and mineral percentages and evaluated for both reflectance or brightness in addition to aspect ratio. Some representative specifications for commercial wollastonite products are shown in Table 1.

PRODUCTION

Wollastonite demand is currently growing both in the United States as well as worldwide, with production capacity in the four major producing countries now about equal to demand (Choate, 1988). Demand is forecast to continue to grow at a rate of about 5% per annum, with the most dramatic growth in high aspect ratio products used in plastics applications. Somewhat slower growth is forecast for paint, ceramics, and other applications.

The United States dominates the world wollastonite market both in terms of production and consumption. About 40% of the domestic production is currently exported, primarily to Europe and Japan. Current domestic consumption is estimated at about 45 kt (50,000 st) valued at roughly \$13 million. Worldwide production in 1987 was about 135 kt (150,000 st). NYCO produced about 45 kt (50,000 st); R.T. Vanderbilt, 27 kt (30,000 st); Wolkem, 23 kt (25,000 st); Partek, 23 kt (25,000 st); and others, 18 kt (20,000 st) (Choate, 1988).

Production typically involves open-pit and/or underground mining using conventional drill/blast techniques. Mining is often of a selective nature and the mined ore is commonly upgraded via hand sorting. Further beneficiation and grinding are often performed at a more centralized location which requires shipping of the lump ore some distance. In some instances, the lump ore is sold as is with further processing performed by the consumer.

While many wollastonite operations are found in proximity to base-metal mines, wollastonite is typically the only economic material produced. However, a possibly salable garnet byproduct is produced at NYCO's New York operations and filler-extender grade calcium carbonate is produced via flotation by Oy Partek. Other potential byproducts

associated with certain wollastonite operations could include tungsten and tin minerals, fluorite, magnetite, base-metal sulfides, etc.

Because of the acicular nature of wollastonite, it is an irritant to the skin and is regulated by OSHA as a nuisance dust. Additional medical evaluations of wollastonite by Sollman and Berger (1988) and the World Health Organization (1987) suggest that there is only limited evidence of carcinogenicity in experimental animals and inadequate evidence of carcinogenicity for humans when exposed to wollastonite. However, there was some decreased pulmonary capacity when comparing wollastonite workers to an unexposed control group. Based on these findings, new regulations governing the production of wollastonite could be forthcoming.

28. Zeolites

RICHARD H. OLSON

COMMODITY DESCRIPTION

Zeolites are highly crystalline hydrated aluminosilicates which have a framework structure enclosing interconnected cavities occupied by relatively large cations and water molecules. More than 30 distinct species of natural zeolite minerals are known and in addition several synthetic species have been manufactured for which there are presently no known counterparts.

The development of synthetic zeolite minerals in the late 1940s and early 1950s (products which were then patent-protected with extremely high profit margins) resulted in the subsequent search for any possible natural analogues. This initial search for possible natural zeolite ores of monomineralic composition was aggressively pursued in the late 1950s and early 1960s and eventually resulted in the knowledge that such natural ores could probably not compete with most of the sophisticated high-value uses of the synthetic products. Similar aggressive exploration efforts in the late 1970s and early 1980s were geared more toward lower-value uses than toward those of the synthetic products and were not generally aimed at replacing them or even partially substituting for them.

GEOLOGY

In the early days of exploration for natural zeolite ores full-time attention was devoted to searches for the space-filling euhedral type of occurrences which are of such keen interest to mineralogists and rockhounds. The best examples of such occurrences are those in the Triassic diabase sills spectacularly exposed as steep to vertical cliffs along the shores of the Bay of Fundy in Nova Scotia. The most detrimental features of such deposits are that they are generally not monomineralic (a compositional feature that would be necessary in order to compete with the synthetics) and would have extremely high mining and beneficiation costs.

In 1958, thanks largely to the discovery of a landmark paper by Bramlette and Posnjak (1933), it was realized that economic natural zeolite ore bodies were much more likely to be found as "single-species" occurrences in diagenetically altered volcanic ash deposits which could be mined comparatively cheaply and would not generally require expensive beneficiation. Virtually all of the attention devoted to the exploration for natural zeolite deposits since early 1958 has been paid to this type of occurrence. Sheppard (1971, 1973, 1983), Sheppard and Gude (1968, 1969), and Munson and Sheppard (1974) describe this type of occurrence in great detail.

Clinoptilolite is far and away the most abundant of the natural zeolite species currently known as occurring in continental deposits. In deep sea deposits, phillipsite is similarly far and away the most common of the known natural zeolite species in such an environment.

Although at least 20 natural zeolite species have been reported as occurring in sedimentary rocks, only 9 of these are known to be at all common. These nine are, listed in the approximate order of decreasing abundance: clinoptilolite (including heulandite), analcime, mordenite, erionite, phillipsite, chabazite, laumontite, and ferrierite.

No byproducts or coproducts are presently known to be

associated with natural zeolite ore bodies. Such are not impossible, however, and might be achieved in the future.

MINING METHODS

Natural zeolite mining is presently performed completely by open-pit methods. It is conceivable that underground mining methods might be employed were a potential substitute for a synthetic product to be discovered in a country where underground mining could be done relatively cheaply, but this would be a relatively rare instance indeed.

Selective mining methods are commonly employed, but several natural zeolite deposits do not lend themselves readily to mechanized mining methods. One deposit in southeastern Arizona has an ore bed on the order of only 15 to 30 cm (6 to 12 in.) thick and is totally hand-mined after the top of the ore bed is encountered and swept clean, as one might do with a warehouse floor. Another deposit in northeastern Nevada has an ore bed only 46 cm (18 in.) or so thick. These are admittedly extremes of thinness, but they do show how thin these exploration targets may be; the greater the value of the product (which may be in dollars per pound), however, the more one can tolerate such extremely thin thicknesses.

GEOLOGY

Most commercial natural zeolite deposits have been formed by the diagenetic alteration of volcanic ash deposits formed in playa lake environments and are therefore generally tabular and concordant in nature. Their geographical distribution, even though generally restricted to desert environments, is nevertheless widespread as compared with most other industrial mineral ores. It is no exaggeration to state that the extent of many, if not most of them, may be expressed in square miles rather than in acres.

GENESIS

The largest and potentially most valuable natural zeolite deposits belong to the "open-system" and "closed-system" types as described by Sheppard (1983). These terms are hydrologic terms: the "open-system" type of deposit is formed by the alteration of volcanic glass by meteoric waters, while the "closed-system" type is formed by the reaction of trapped connate water with the volcanic glass. The future economic potential of natural zeolite deposits appears to be largely restricted to those of these two systems; therefore, this discussion will only consider these two.

Both of these types of natural zeolite deposits are zoned and one who attempts to mine them should be aware of this feature. In the "open-system" type, a vertical zonation of authigenic silicate minerals is common. With the "closed-system" type, there is commonly a basinward lateral zonation from unaltered volcanic glass to zeolites and finally to potassium feldspar in the central portion of the basin.

The genesis of most potentially commercial natural zeolite ores is relatively simple, i.e., a pseudomorphic replacement of amorphous volcanic glass by highly crystalline zeolite minerals. It is likely that most such deposits were at their purest when they were formed and that virtually all of the deleterious included material in such ores was formed secondarily over geologic time. A common method of for-

mation of such deposits results in a zonal arrangement related to the original configuration of the depositional basin; consequently, care must be taken not to mine outside of the zeolite zone and therefore include extraneous material in the mined ore.

Natural zeolite deposits are invariably quite young geologically, for such minerals are not time-stable. It is likely that no commercial natural zeolite deposit older than Cretaceous will ever be found.

STRUCTURAL CONTROLS

The tabular and concordant nature of natural zeolite ore bodies dictates that their mining is relatively simple. Many of them can be traced along strike for several miles and steep dips are uncommon except where block-faulting, associated with nearby mountain-building, has taken place. Folding of the strata seldom complicates the life of the zeolite miner, but block-faulting commonly does. Grade control is not easily accomplished because visual inspection alone generally can not aid in the determination of whether ore minerals are present or absent. Virtually all natural zeolite samples must be subjected to X-ray diffraction analysis in order to determine whether or not they may represent potential ore.

EXPLORATION

Airborne reconnaissance is useful in the exploration for natural zeolite deposits, particularly in areas where the desert basins have little topographic relief and difficult road access. Areas of interest, which can commonly be readily identified from the air by their light color and overall geological habit, are spotted upon maps or aerial photographs. Follow-up visits are then made on the ground.

Even though visual identification of just which zeolite species may be present is difficult, if not impossible, to achieve in the field with either the hand lens or even with the petrographic microscope, the geologist with a little field experience will soon be able to discern with a high degree of success whether or not the precursor rock has been zeolitized at all. This is a subjective art and can not really be taught, but it can be developed in the interested neophyte by visiting many known deposits and manually working with such ores.

Compared with most other ores, the exploration for natural zeolite ores is relatively simple. A thorough literature search is desirable, followed up by visits to governmental and academic agencies and institutions in order to consult with past and present workers in either natural zeolites or in geological systems associated with the formation of natural zeolites.

29. Zirconium/Hafnium*

Zirconium and hafnium are curious elements because they are almost always found together in nature. Zirconium was discovered by Klaproth in 1789 and isolated 35 years later by Berzelius. Because hafnium's chemical properties are so close to those of zirconium, it was not discovered until 1923 when Coster and Von-Heressey detected it using X-ray spectrographic analysis. These elements occur most commonly in nature as the mineral zircon (ZrSiO_4) and less commonly as the oxide baddeleyite (ZrO_2). They also are found as a variety of other silicates. Zircon was identified as a component in alluvial and beach sands in 1895, but it was not produced in any quantity until 20 years later. Zircon is always a coproduct from TiO_2 mining and processing. During World War I it was produced as a coproduct of beach sand mining for titanium minerals just south of Jacksonville Beach, FL, and was patented as a refractory. It was not until the 1930s when Zircon Rutile, Ltd. began mining at Byron Bay on the east coast of Australia that zircon was first used as a foundry sand. Later in the 1940s, NL Industries, Humphreys Gold Corp., and E. I. du Pont de Nemours & Co., Inc. began production of zircon sands from fossil beaches in northeast and northcentral Florida. Baddeleyite first became available as a commercial product in 1916, but never in the quantity of zircon.

Zircon holds a unique position as an industrial mineral because it is used for both its physical and chemical properties as well as an ore of zirconium and hafnium metals. Australia is the major zircon producer followed by South Africa and the US. Zircon is also produced in India, Sierra Leone, Sri Lanka, Malaysia, China, Thailand, and Brazil. Undeveloped heavy mineral beach sand reserves containing zircon are known to occur in Egypt, Malawi, Senegal, and Tanzania. Locations are shown in Fig. 1.

MINERALOGY

Zirconium and hafnium are always present together in naturally occurring compounds. Most commonly they form as the silicate sometimes containing iron, calcium, sodium, manganese, and other elements. Less commonly they are found as oxides in combination with titanium, thorium, calcium, and iron. Zircon is the most common form. It is extremely resistant to weathering; therefore, it is often present in ancient beach sands and placer deposits. Although resistant to alteration from external sources, it is vulnerable to internal alteration as the result of thorium and uranium substituting for zirconium either in the zircon lattice or in solid solution. Alteration to the metamict state takes place as radioactive emanations from these elements disorder the crystal lattice, accompanied by hydration, reduction in specific gravity, and changes in color. The mineralogy of zircon and baddeleyite and variation of physical and chemical properties are shown in Table 1.

The effects of zircon's internal alteration and darkened color can be corrected by heating to 1000°C for 30 min or so. A certain time-temperature relationship makes it possible for decolorization and reordering of the crystal lattice to take

place when heating at higher temperatures for shorter periods or at lower temperatures for longer periods. After heating, X-ray diffraction patterns are sharper, the grains may be harder, and, except for particles of malacon, the grains will be white or colorless in the absence of grain surface coatings. The color change is only temporary and the particles slowly darken with time.

Zircon fluoresces light yellow in shortwave ultraviolet light. If exposed to ultraviolet light for extended periods of time, white (calcined) zircon turns purple. With time the induced color begins to fade and eventually disappears (e.g., calcined Florida zircon exposed to ultraviolet light for 24 hr still retains faint, but discernible, purple color after six months).

OCCURRENCE OF ZIRCON AND BADDELEYITE

Commercial zircon is available only in the form of sand mined, for the most part, from ancient beach sand deposits. In the beginning, zircon occurs as an accessory mineral in a variety of igneous and metamorphic rocks, especially those containing sodic feldspars such as granite, syenite, diorite, etc. It is one of the earliest minerals to crystallize from a cooling magma and frequently incorporates inclusions (e.g., apatite, magnetite). The zircon in these rocks often crystallizes out in tetragonal prisms with pyramidal terminations but it also commonly occurs as rounded grains in igneous rocks. It is sometimes found in metamorphic rocks such as gneiss and schists. One occurrence has been reported in a meteorite.

Before the zircon particles can become part of a beach sand deposit, their host rocks must undergo a series of events that will ultimately liberate the zircon for transportation to a seacoast. This begins with the exposure of the host rocks to subaerial weathering. The rocks are broken down into smaller fragments and transported downhill by rainwater and gravity. The rocks further decompose to the point at which the smaller zircon grains are liberated from the enclosing feldspars and quartz. The mineral particles are transported by streams and ultimately end up along a marine shoreline. Here the action of waves, tidal currents, and wind may remove lighter quartz, forming a heavy mineral deposit rich in zircon. Many of the older beach sand deposits have been consolidated and the grains cemented together to form sandstones containing concentrations of titanium minerals, zircon, monazite, and other heavy minerals. Deposits such as these occur in the four-state area of Utah, Wyoming, New Mexico, and Colorado. Since this type of deposit requires more costly mining methods, crushing, and grinding, they are less attractive for mining and exploitation than are the more recent less consolidated deposits. All of the commercial zircon products today are mined and separated from relatively young beach sand deposits occurring on or near active coast lines.

Australian Zircon Deposits

Australia is the major world producer and exporter of zircon sand. Deposits are found on both the east and west coasts of Australia. In eastern Australia major heavy mineral sand deposits lie between Broken Bay, New South Wales, to the south and Cape Clinton north to Rockhampton, Queensland. The richest occurrences are concentrated in the area between Yamba and North Stradbroke Island. Although

*Excerpt from Garnar, T.E., Jr., 1983, "Zirconium and Hafnium Minerals," *Industrial Minerals and Rocks*, 5th ed., Vol. 2, S.J. Le-fond, ed., AIME, New York, pp. 1433-1446.

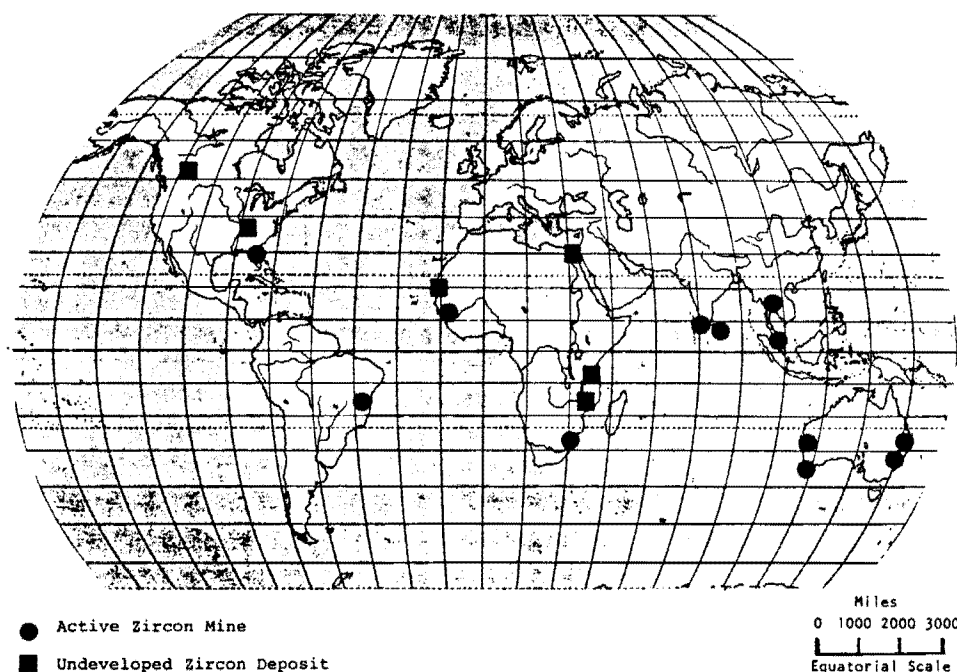

Fig. 1. Location of world zircon deposits

there had been production of zircon from a mine at Ponte Vedra, FL, between 1918 and 1929, the east Australian mines were the first major producers of commercial zircon sands beginning in the 1930s.

The east Australian heavy mineral beach sands deposits are of both Pleistocene and Holocene age. Zircon and its coproduct rutile have been derived from the breakdown and erosion of well sorted silica sandstone in the late Paleozoic and Mesozoic basins of eastern Australia. Zircon-bearing sands as mined contain less than 0.5% zircon. Zircon from the east coast of Australia ranges in color from dark tan to pale lavender. Because of iron-bearing grain surface coatings, these zircon sands become brownish orange to orange on heating to 1000°C. Grain size and shape vary from deposit to deposit. The eastern Australia zircon is characterized by subangular to rounded particles with many elongated prismatic grains. Particle size ranges from 90 to 100 μm depending upon which mine produced the zircon. Until 1983, five companies produced zircon from beach sands along the east coast of Australia. Two have since shut down.

Mineral sand deposits of Western Australia are found along ancient beaches which lie at different elevations ranging from 10 to 200 m above present sea level. The strand line deposits are part of a series of Pleistocene and Recent sediments which exist as a thin veneer throughout the Perth basin. These overlie much older marine and continental deposits. Shoreline deposits formed during stable Pleistocene sea level stands. The age of these deposits ranges from fairly young to perhaps over a hundred thousand years. Heavy mineral sand deposits along the southern coast of Western Australia near Cable and Bunbury are very rich in the mineral ilmenite ($\text{Fe}_2\text{O}_3 \cdot 3\text{TiO}_2$) but contain some zircon.

Zircon has become a major export of Western Australia since the discovery of the deposits near the town of Eneabba. The Eneabba heavy minerals occur at different strand lines ranging from 82 to 120 m above sea level. The presence of clay, induration, and grain surface coatings created difficult mining and mineral separation problems; however, these have largely been corrected by the producers. The mineral grains are extensively coated with ferruginous aluminum silicates

Table 1. Mineralogy of Zircon and Baddeleyite

	Normal Zircon	Altered Zircon (Hyacinth)	Much Altered Zircon (Malacon)	Baddeleyite
Crystal	Ditetragonal Dipyramidal	Ditetragonal Dipyramidal	Amorphous	Monoclinic Prismatic
Specific gravity	4.6-4.7	4.2-4.6	3.9-4.2	5.4-5.7
Mohs hardness	7.5	7	6-7	6.5
Color	White	Purplish	Dark	Variable
Index of refraction	1.92-1.96	1.90-1.92	1.76-1.90	2.19
Cleavage	110 poor	110 poor	None	001 Perfect
Loss on ignition	0.1%	0.5-1%	10%

as a result of laterization. The grain surface coatings cause the zircon to take on a light orange color when heated to 1000°C.

South African Deposits

Heavy minerals are produced from a high dune paralleling the Indian Ocean about 160 km north of Durban. The ore body being mined is 17 km long and 2 km wide and is reported to contain 700 million tons of ore. Life of the present ore body is estimated at 30 years.

The zircon grains are rounded to irregular or prismatic in shape and are slightly finer than Du Pont Florida zircon but coarser than Associated Minerals, US. Like Australian zircon the grains have surface coatings which turn a dark orange color on heating.

There are reported to be similar concentrations of heavy minerals in dunes to the north of Richards Bay.

Baddeleyite is recovered from mill tailings at the Palabora copper mine in the Transvaal. The ZrO_2 and HfO_2 range from 97 to 99%.

Baddeleyite may occur either as a primary or secondary mineral. It is sometimes found in alluvial deposits associated with ilmenite, zirkelite (mixture of zircon and baddeleyite), apatite, and perovskite. It is also found in Brazil, Sri Lanka, Italy, and the United States.

US Deposits

A small amount of zircon was produced from a beach sand mine located near Ponte Vedra, FL, between 1918 and 1929. There were no companies producing heavy minerals in Florida from 1929 to 1939. In 1940 a small quantity of heavy minerals including zircon was produced from surface concentrates found in the beach sand near Melbourne, FL; this operation was later moved to a dune area near Vero Beach and operated until about 1963. Between 1943 and 1963 zircon was produced from a deposit at Arlington, a suburb of Jacksonville, FL. In 1963 production began from a heavy mineral deposit near Folkston, GA. When this deposit was mined out in 1974, the mining and concentrating equipment was moved a few miles south to a deposit near Boulougne, FL, where mining continued until the ore was mined out in 1979. Zircon production began from an old shoreline deposit near Green Cove Springs, FL in 1973. Zircon from this deposit averages about 98 μm in size. This is similar to the zircon produced from the Jacksonville deposit during World War II.

The largest domestic supply of zircon sand comes from the Trail Ridge deposit in north central Florida. This large deposit was discovered by Du Pont in 1946 and has been in continuous production of zircon since 1950. The deposit was formed at the height of Florida's submergence during Pleistocene times. Reworked sands transported from older sand features were redeposited forming the ridge. Waves, currents, and wind action removed part of the lighter silica sand, leaving an enrichment of heavy minerals in sand dunes on the western flank of this prominent geographic feature. After deposition of the heavy mineral-bearing sands, the ridge was covered with wind blown sand, forming an overburden.

Zircon from the Trail Ridge deposit is extremely uniform with respect to particle size and grain morphology as well as chemical purity. The grains are free of surface coatings and have been slightly etched as a result of wind action during formation of the deposit. The grains have no surface coatings, therefore, the zircon turns white on heating.

Undeveloped zircon deposits are also known to exist in western Tennessee.

Major world zircon sand producers are listed in Table 2.

Hafnium Metal

Hafnium, though relatively abundant in nature, is sparsely disseminated and very costly to extract. Zircon sand is the only commercial source of this metal. Hafnium's melting point is 4000°F, which is higher than the melting point of zirconium. Heat-resisting parts for special purposes have been made by compacting hafnium powder to a density of 98%. The metal has a close-packed hexagonal structure. It has excellent resistance to a wide range of corrosive environments. Because of its high thermal neutron-capture cross section and excellent strength up to 1000°F, hafnium is useful in unalloyed form in nuclear reactors.

WORLD ZIRCON RESERVES

The US Bureau of Mines reports identified world resources of zircon exceed 60 million tons; however, only a small fraction is economic to mine. Of this 60 million tons, the US has about 14 million tons. Studies of zircon associated with phosphate, sand, and gravel have been carried out by several US governmental agencies and private interests. In all cases the tonnage of zircon and other heavy minerals produced in those industries is insufficient to be considered economic at this time. An important future source may be Canada tar sands. Although the percent heavy minerals in the tar sands is less than 1, about 41,000 st of zircon could be produced from the 95 million st of tar sands mined annually.

THE FUTURE OF ZIRCON IN NORTH AMERICA

The demand for zircon will be set by the needs of the various consuming industries and by the availability of equal or lower cost alternative products.

The supply of zircon will be determined by demand for titanium minerals and availability of deposits. It is doubtful that new heavy mineral mines will open until the current oversupply of rutile and zircon passes and prices stabilize at higher levels. Several known deposits have already been put off limits. Others may be eliminated if governmental attitudes toward mining and the environment follow the trend of the 1970s.

Additional North American reserves are available for development to meet domestic needs. These will be developed if the delivered cost of the zircon and other heavy minerals is competitive with that from foreign sources and yet high enough to provide producers a reasonable return on their investment.

2.11 Acquisition and Exercise of Rights to Use Land in Connection with Surface Mining Operations

CLAYTON J. PARR

INTRODUCTION

This section deals with the acquisition, maintenance, and exercise of rights to make use of lands in connection with surface mining operations. It is presumed that the mineral rights necessary to exploit an ore occurrence have been obtained and that the focus has shifted to considerations of land use.

At a surface mine, land is needed for uses related both to mineral extraction activities and to mining related activities. Property rights are required for stripping beyond the ore zone, and for waste dumps, leach piles, ore storage, ore transportation systems, haul roads, crushers, and other mine related purposes. Space is also needed for mine support facilities such as maintenance and repair shops, warehouses, mine offices, change houses, equipment storage areas, power substations, and water storage and distribution systems. A mill will require a separate set of property rights, the most critical of which are those needed for tailings disposal.

Often, the operator already holds most of the needed lands through mining claims or mineral leases. If they do not provide the necessary rights to conduct mining and mine related activities, or if additional land is needed, then independent methods of land acquisition must be utilized.

For a discussion of methods for acquisition of mining rights, reference can be made to "Mining Law," Section 2, in the *Mining Engineering Handbook*, published in 1973 by the Society of Mining Engineers of AIME.

FEDERAL LANDS

Unpatented Mining Claims

If unpatented mining claims are included in the mine project area, they might provide convenient sites for mine related surface activities. The original federal mining law provides that the owner of an unpatented mining claim has exclusive possessory rights of all the surface within the boundaries of the claim.¹ Notwithstanding several judicial decisions invalidating claims used solely for nonmine related uses,² claim owners commonly used the surface of claims for other purposes, especially for cabin sites. That possessory rights which accompany a mining claim do not include the right to conduct nonmine related activities was clearly established by the Multiple Surface Use Act of 1955.³ This Act provides that any mining claim located after July 23, 1955 "shall not be used, prior to issuance of patent, for any purposes other than prospecting, mining, or processing operations and uses reasonably incident thereto." The Act further provides that rights under any mining claim thereafter located will be subject, prior to the issuance of patent therefor, "to the right of the United States to manage and dispose of the vegetative surface resources thereof and to manage other surface resources thereof (except mineral deposits subject to location under the mining laws of the United States)." Thus, the uses that may be made of the surface of an unpatented mining claim are limited to those reasonably related to the development and extraction of minerals.⁴

The right to make use of the surface of an unpatented

mining claim in aid of mining, however, is not without its limits. Surface use activities for mining purposes must be performed in good faith.⁵ Thus, if a claim were located solely for the purpose of surface use, it might be said not to have been located in good faith, and therefore be subject to challenge by the United States.⁶ In addition, according to recent authority, mining related activities on a claim may be proscribed if they are determined to be unnecessary and unreasonably destructive to surface resources.⁷

Some uncertainty exists relative to the use of an unpatented claim in connection with mining on other properties. Even where a claim is located in good faith, if it is subsequently used for mine related purposes incident to the extraction of minerals outside of the claim, then, although the law is not entirely clear on the subject, the operator takes the risk that the activity might be enjoined and damages in trespass awarded.⁸ Generally, however, if a claim has been located in good faith for its mineral potential and is part of a mineralized block that is covered by a valid mining plan, there is little risk of a challenge to reasonable mine related surface use. That risk could be sufficient, however, to necessitate consideration of alternative land acquisition procedures.

An inherent risk in using any unpatented mining claim for mine ancillary purposes is that ownership may be lost relatively easily as compared to other forms of land ownership. For instance, the claim may be invalidated by reason of noncompliance with federal location and claim maintenance requirements or the claim may be subject to forfeiture to a junior locator for failure to perform annual assessment work.

Every unpatented claim must be independently supported by a valid discovery of minerals.⁹ A claim not supported by a legally sufficient discovery is subject to challenge by a subsequent locator who is better able to demonstrate a discovery,¹⁰ by a conflicting user through a private contest,¹¹ or by the United States through a government initiated contest.¹² The basic legal standard for discovery is the so-called *prudent man* test which examines whether the minerals are of such a character that a person of ordinary prudence would be justified in the further expenditure of his labor and means, with a reasonable prospect of success in developing a valuable mine.¹³ In a government initiated contest, the claimant must also be able to show that by reason of accessibility, bona fides in development, proximity to market, existence of present demand, and other factors, the deposit is of such value that it can be mined, removed, and disposed of at a profit.¹⁴ These tests require that there be an actual physical exposure of mineral-bearing rock in place within the limits of a claim.¹⁵ An important maxim to remember is that information sufficient to justify additional exploration is not enough to establish a discovery, at least as against the United States.¹⁶ Clearly then, use of an unpatented mining claim for mine related purposes carries with it an inherent risk that the claim might not be able to withstand careful scrutiny as to whether it is supported by a legally sufficient discovery.

An unpatented mining claim can also be lost if legally

sufficient annual assessment work is not performed.¹⁷ Although failure to perform valid annual assessment work has been thought only to render a claim subject to forfeiture to the locator of an overlapping junior claim, the United States has asserted a separate right to declare a claim cancelled when assessment work has not been performed.¹⁸

It is common practice in a mine area to utilize mine work on a few claims as assessment work for a much larger group of contiguous claims. Group assessment work is valid, however, only if the work performed off of any particular claim benefits or tends to benefit that claim and is done for the purpose of developing each claim in the claim group.¹⁹ This direct benefit requirement is sometimes difficult to establish where the claim is being maintained or being utilized primarily for mine related purposes without being projected for mining pursuant to an overall mining plan.

Loss of a claim can also result from failure to make annual filings of evidence of performance of assessment work with the local county recorder and the Bureau of Land Management.²⁰

A more serious problem relative to rights of surface use is presented where the mining claim has been located on land which has been patented by the United States subject to a reservation of minerals. Since the subject relates to both mining claims and federal mining leases, it is discussed separately later in this section.

Millsite Claims

Millsites provide a simple, straightforward method for acquiring federal land for use in connection with mining operations. Because the location of a millsite is a self-initiated right, however, it is, like a mining claim, of tenuous validity and therefore often lacking in the security of title necessary for a major investment.

Three types of millsite claims are recognized in the federal mining law. They are:

1. Nonmineral land not contiguous to a vein or lode used or occupied by the proprietor of a lode mining claim for mining or milling purposes;
2. Nonmineral land not contiguous to a vein or lode appropriated by the owner of a quartz mill or reduction works; and
3. Nonmineral land used or occupied by the proprietor of a placer claim for mining, milling, processing, beneficiation, or other operation in connection with the placer claim.²¹

Thus, a millsite must be tied to a lode or placer mining claim, or be used specifically for a quartz mill or reduction works.

The terms *quartz mill* and *reduction works* have been interpreted strictly by the Department of the Interior to refer literally to plants that crush quartz rock for the extraction of gold, or to plants that reduce metals from their ores, such as smelting works or cyanide plants.²² It is questionable, therefore, whether a conventional base or precious metal concentrator is a *reduction works*. Thus, *independent* millsite claims are not commonly used because of the fear that the desired use will not fit the narrow definitions. Accordingly, most millsites are used in connection with lode or placer mining claims.

Millsites can be located in plots up to 2.02 ha (5 acres)²³ utilizing location procedures similar to those for lode or placer claims.²⁴ The land must be unappropriated public domain open to location under the mining laws.²⁵ Reference must be made to the laws of the state involved in order to find out the precise requirements for location. Generally, there is no specific dimensional configuration required for a

millsite, but usually they are in square or compact rectangular configurations.

The land upon which a millsite is located must be non-mineral in character. This can pose problems with respect to millsites located in close proximity to a mine site since the likelihood of mineralization is greater in such areas. The risk of a determination that the land is mineralized is that the millsite claim can be declared to be void through a contest proceeding. Mineralization on millsite lands also creates a risk that the land might be appropriated through a lode or placer mining claim located by another party. A millsite can be located on lands known to be valuable for leasing act minerals.²⁶

Although the rule is not free from doubt, as against junior locators, the mineral or nonmineral character of the land is determined at the date when rights to a millsite attach, which would be the date of location of the millsite if the millsite is put to immediate use, or if not, the date when use or occupation for use begins.²⁷ With respect to the United States, however, a millsite claim can be defeated if mineralization is found at any time prior to the issuance of a patent.²⁸ The presence of mineralization can be established with less information than is required to demonstrate a discovery of valuable minerals.²⁹

Some persons have attempted to reduce the risk of invalidation by locating lode or placer claims over millsite claims.³⁰ That practice is not encouraged, however, because the location of the mining claim can be construed as an admission that the land covered by the millsite is mineral in character.³¹

An additional consideration that might influence the use of a millsite is that in order for a millsite claim to be valid the lode or placer claim serving as the basis for the millsite must be valid. Accordingly, if an unpatented lode or placer claim is determined to be invalid, a dependent millsite attached to that claim also will be invalid.

The requirement of noncontiguity has been interpreted fairly loosely and usually will not pose a problem where there is some slight contact between the millsite and the mining claim which is not outright boundary-to-boundary overlap.³²

There is no maximum number of millsites that can be held, but the number can be limited by considerations of good faith and reasonable need.³³ Only as much ground may be included in an individual millsite as is actually needed for the particular use involved, but a paring down of a millsite for such reason would ordinarily occur only in connection with a patent proceeding.³⁴

The contemplated use of the millsite must be a "mining or milling purpose" under the statute.³⁵ Generally all that is required is that the use be some step in, or directly connected with, the process of mining or milling.³⁶ Millsites can be used for facilities related to the acquisition and exercise of a water right, but they cannot be used for purposes which would ordinarily be permitted under an easement, such as roads, transmission lines, and pipelines.³⁷ There is some uncertainty as to whether a millsite can be obtained and used exclusively for the deposit of waste.³⁸

Read literally, the statute requires that a millsite's validity be sustained by an actual continuing use.³⁹ Mere intention or purpose of performing acts of use or occupancy will not satisfy the statute.⁴⁰ A reasonable time to make use of a millsite claim will be permitted,⁴¹ but in practice, a millsite will almost have to be located well in advance of the date when the mine related activity is commenced. Although there is a question as to the validity of an idle millsite, a prospective use designated specifically in a mine plan might be sufficient

to protect the millsite. The validity of a millsite will nevertheless remain tenuous until an actual use is commenced, and then it is only secure as long as that use is continuous.

It is not necessary that annual assessment work be performed on a millsite; however, a notice of intent to hold must be filed each year both in the county records and with the Bureau of Land Management pursuant to regulations of the Bureau of Land Management.⁴²

A millsite may be patented, but only after or contemporaneously with the issuance of a patent on the associated mining claim.⁴³ The validity tests described above will be applied most strictly during the course of a patent proceeding.

Federal Mineral Leases

As is the case with any other situation where mining rights are held pursuant to a lease, reference must be made to the language of the lease itself in the first instance to determine what rights exist relative to use of the surface in aid of mining operations. Typically, the granting clause of a federal lease gives the lessee the right to construct and maintain on the leased lands such structures or other facilities as may be necessary for the mining, preparation, and removal of the leased minerals. This right may be expanded to include the right to construct and maintain works, buildings, plants, structures, and appliances necessary to the mining, processing, and removal of the deposits. The express grant of the second right is important, because reference to processing as a permitted use removes doubt as to whether concentrators or other mineral processing facilities can be constructed on the premises.

Although federal leases are generally issued on standard forms, specific provisions, often imposing onerous burdens, are added in the form of special stipulations. The stipulations can impose detailed requirements, particularly with respect to surface protection and reclamation and especially where national forest lands are involved. Newer leases involving minerals whose mining may cause widespread land disturbance, such as oil shale and tar sands, are likely to have extensive stipulations.

The real governing factor in defining the right of surface use is the regulatory approval that must be obtained for any proposed mining or mine related activities. Applicable regulations require an operator to submit a detailed mining plan for approval before conducting any operations under a federal mineral lease.⁴⁴

Under BLM rules published in Part 23 of Title 43, Code of Federal Regulations, the mining plan is submitted to the mining supervisor, but he must consult with the other agencies involved and the BLM district manager with respect to surface protection and reclamation requirements before approving the plan.⁴⁵ The plan must describe proposed methods of operating, including a description of proposed roads or vehicular trails and the size and location of structures and facilities to be built, and it must provide information about water use and contamination, erosion control procedures, and environmental impact mitigation control measures.⁴⁶ Details must be provided relative to the timing and methods of reclamation and revegetation.⁴⁷

Additional BLM regulations that relate primarily to mining considerations are set forth in Part 3570 of Title 43, Code of Federal Regulations. They require that the plan include information relative to mining design and operation, and also data concerning runoff and water pollution control, mitigation measures for the protection of fish and wildlife, and a plan of reclamation.⁴⁸

Before approving a mine plan, the authorized officer must

consult with the agency having administrative jurisdiction over the lands concerning surface protection and reclamation.⁴⁹ This process could create additional requirements for information and additional burdens in the way of mitigating adverse environmental impacts.

If the mining plan is approved, the operator must provide a performance bond before commencing operations, to ensure that commitments made in the mining plan are carried out.⁵⁰

Although grants of surface use rights in individual leases seem to refer to mining on the leased tract itself, approval for use of the leased lands in whole or in part in aid of mining on other federal leases can be approved on a site specific basis. If, however, the surface of such federal leased lands is held under private ownership, then a new problem arises. Surface owners whose rights derive from patents issued under the Coal Acts of 1909 and 1910, the Agricultural Entry Act of 1914, and the Stock-Raising Homestead Act of 1916 can prevent use of the surface of the tract involved to support simultaneous or independent production on other lands.⁵¹

Special purpose leases providing for the use of surface rights can be obtained in connection with mining on federal phosphate and sodium leases.⁵² A phosphate lease holder can obtain up to 32.4 ha (80 acres) of land if the Secretary of Interior determines that the lands are necessary or convenient for the extraction, treatment, and removal of phosphate deposits.⁵³ Tracts can be in separate plots so long as they do not exceed 32.4 ha (80 acres) in the aggregate. The lands cannot be included in a National Forest.

A sodium lease holder may obtain rights to use a single tract of unoccupied nonmineral public land for campsites, refining works, and other purposes connected with and necessary to the proper development and use of deposits covered by the permit or lease.⁵⁴

Surface Use Where the United States Has Issued a Patent Subject to a Reservation of Minerals

The federal government has issued land patents to private owners with a reservation of minerals to the United States under the coal acts of 1909⁵⁵ and 1910,⁵⁶ which apply to coal only, and the Agricultural Entry Act of 1914,⁵⁷ the Stock-Raising Homestead Act of 1916,⁵⁸ and the Taylor Grazing Act of 1934.⁵⁹ Special procedures must be followed with respect to locating and operating mining claims on such lands, and in conducting operations thereon pursuant to federal mineral leases. This discussion focuses on the Agricultural Entry Act of 1914 and the Stock-Raising Homestead Act of 1916.

Patents issued under the Stock-Raising Homestead Act of 1916 contain a reservation to the United States of all minerals in the lands and the right to prospect for, mine, and remove the same.⁶⁰ A party who has located mining claims or obtained a federal mineral lease on lands patented under the Stock-Raising Homestead Act can reenter the tract involved and occupy as much of it as may be required for mining. Before the reentry, however, the claimant must (1) secure written consent or waiver of the surface owner, (2) make an agreement with the surface owner for payment of damages to crops or other tangible improvements, or (3) execute a bond or undertaking to the United States for the benefit of the owner.⁶¹

The Agricultural Entry Act of 1914 allowed entry of lands withdrawn as phosphate, nitrate, potash, oil, gas, sodium, sulphur, or asphaltic minerals lands or classified as valuable for those deposits, with the proviso that a subsequent patent would be subject to a reservation to the United States of the deposits on account of which the lands were withdrawn

or classified or reported as valuable, together with the right to prospect for, mine, and remove the same.⁶² Where there has been a reservation under the Act, the mine operator operating under a federal lease for the reserved minerals must make payment of damages to the owner or give a good and sufficient bond or undertaking therefor in an action instituted in any competent court to ascertain and fix damages.⁶³

Much uncertainty has existed under these two acts as to the extent of use that may be made of the patented land by a mineral interest holder and the amount of compensation that must be paid for damages. Generally, the mineral developer can use the entire surface so long as such use is necessary and reasonable for the extraction of minerals from the associated tract of land.⁶⁴ Although the question is not entirely free of doubt, surface mining is considered to be permissible if it is reasonable and necessary for the recovery of the reserved minerals.⁶⁵ The method adopted in exercising rights of surface use, however, must be necessary and cannot result in use of more of the surface than is reasonably required.⁶⁶ Whether the use is excessive or in fact permitted at all under the law is subject to determination on a case-by-case basis. For example, the right to "mine and remove" minerals has recently been interpreted as encompassing the right to construct a geothermal power plant,⁶⁷ but the extent to which the decision of the court will be applicable to processing of other kinds of minerals remains to be seen.

A mining claim holder or mineral lessee does not have a right to make use of the surface of patented land to support simultaneous or independent production on other lands.⁶⁸

Patentees under the various acts are entitled to compensation for damages caused by the mineral claimant or mineral lessee to "crops and improvements" under the Agricultural Entry Act⁶⁹ and to "crops and tangible improvements"⁷⁰ under the Stock-Raising Homestead Act. Because the "improvements" were clearly contemplated to be agricultural improvements, the Supreme Court of the United States held in 1927 that compensation for nonagricultural improvements need not be made.⁷¹ It is not clear, however, that the rule in that case would be extended to all nonagricultural improvements or that it would be applied so rigidly in a modern setting.⁷² Since 1949, compensation is also payable in respect of damage that may be caused to the value of the land for grazing purposes by removal of the reserved minerals by strip or open pit mining methods.⁷³

Because of the tenuous nature and uncertain extent of the rights of a mining claimant or federal mineral lessee to make use of the surface of lands patented with a reservation of minerals in the United States, it is standard practice to enter into a surface use agreement with the surface owner in such situations, such as is described later in this section. A forced entry procedure becomes necessary only when attempts to arrive at an agreement with the surface owner have been unsuccessful.

Special Procedures for Federal Lands

Land Exchanges: Authority has been granted to the Secretary of the Interior with regard to Bureau of Land Management administered lands and to the Secretary of Agriculture with regard to lands in the National Forest System, to dispose of public land or interests therein by exchange.⁷⁴ The exchanged lands must be in the same state, and there must not be a difference in appraised value of the exchanged tracts greater than 25%.⁷⁵ That difference can be made up in cash equalization payments running either way.⁷⁶ Thus, a mine operator can purchase lands that are desired by the

BLM or the US Forest Service and exchange them for needed federal lands in the same state of near equivalent value in the vicinity of a mining operation.

BLM exchange procedures are established in Part 2200 of Title 43, Code of Federal Regulations; those of the Forest Service are in Section 254 of Title 36, Code of Federal Regulations.

Exchange procedures, although workable, are lengthy and complex, thereby limiting their usefulness. Even though the Secretaries of Interior and Agriculture must consider the public interest in acting upon exchange applications,⁷⁷ the procedure is subject to the vagaries of a complex administrative process. Because of the long time periods required between initiation and completion of the transaction, the approach is feasible only if the contemplated need can be deferred for several years, or if interim rights to the land can be acquired under millsite claims or temporary permits.

Before any decision is made about seeking a land exchange, contact should be made with local representatives of the US Forest Service or the District Office of the BLM. The initial inquiry will reveal whether certain lands are desired by these agencies that might be suitable for purchase and exchange for federal lands near the mine site. The interest acquired for exchange need not necessarily be the entire fee title but could be a lesser interest such as water rights, or easements for roads and trails. Informal negotiations with the District Ranger can be culminated in a more formal Statement of Intent that spells out the basic understanding reached by the parties.⁷⁸

If these informal negotiations are successful, a formal land exchange proposal complying with the regulations is then prepared. Of the numerous steps that follow, the most important is the appraisal process which determines the current fair market value for the lands or interests in the lands subject to the exchange.

Surface Use of BLM Lands by Lease, Permit, or Easement: The Secretary of Interior has authority to issue easements, permits, leases, and licenses for "the development of small trade or manufacturing concerns."⁷⁹ Rights can be obtained under this authority for many miscellaneous mine-related uses. Those that require rights-of-way for linear type uses would ordinarily be obtained under rights-of-way provisions described later in this section.

The nature of the right granted is tailored to the use for which the land is needed. If there is to be substantial construction and the investment of a large amount of capital, a *lease* will be issued for a specific term consistent with the time required to amortize the capital investment. If the use is for a short term not to exceed three years, and involves little or no construction or investment, a *permit* will be issued. A permit may be renewed or revoked. Nonpossessory and nonexclusive *easements* can be granted to provide rights for limited linear type uses that are not covered under other regulatory provisions. Short-term noncommercial activities that do not appreciably damage the lands are considered to be *casual uses* for which no formal approval is required.⁸⁰

Rights granted under these provisions are essentially negotiated contracts consistent with the regulations in Part 2920, of Title 43, Code of Federal Regulations. Processing is begun by informal discussions with the Bureau of Land Management District Office having jurisdiction over the public lands in question. It is possible at this stage for the authorized officer to issue a permit for a land use if the proposed use is in conformance with Bureau of Land Management plans, policies, and programs, local zoning ordinances, and any other pertinent requirements, and will not cause appre-

ciable damage or disturbance to the public lands, their resources, or improvements.⁸¹

If a more permanent right is required, formal processing is initiated by the filing of a proposal by the person desiring to make the land use.⁸² The proposal is then thoroughly reviewed to evaluate the appropriateness of the proposed use, particularly with respect to BLM land use plans, which must have been completed for the area in question.⁸³

Barring any problems, the initial approval step is then taken by the BLM through publication of a Notice of Realty Action indicating the availability of public lands for nonfederal uses through lease, permit, or easement.⁸⁴ Formal applications can then be submitted by the person who initiated the process and by other interested parties.⁸⁵

If interest is expressed by several parties, the authorization may be offered on a competitive basis, and if not, on a negotiated, noncompetitive basis.⁸⁶ This decision is mainly a matter of judgment on the part of the authorized officer.⁸⁷ In any event, the proposal by the person selected must not be for less than fair market value.⁸⁸

Terms and conditions are then prepared consistent with the regulations.⁸⁹ Rental fees are to be paid annually in advance based on fair market value or as determined by competitive bidding.⁹⁰

An important factor in deciding whether to go through this process is that the land use applicant must reimburse the United States for reasonable administrative and other costs incurred in processing the application and in monitoring construction, operation, maintenance, and rehabilitation of authorized facilities including, if required, costs of preparing an environmental impact statement.⁹¹ These costs can be substantial and should be evaluated before an attempt is made to use procedures of this type.

In general, even though the procedures may be onerous, acquisition of lands through this method may be the most appropriate for many uses required in connection with a mining operation. Because it is frequently desirable to obtain title ultimately to lands that will be the subject of a large investment, emphasis may be placed on other methods that lead to the acquisition of title such as land exchanges. Even in such cases, temporary rights might be obtained under these regulations that will permit the desired use pending the ultimate acquisition of title.

Rights-of-Way on BLM Lands: The Secretary of the Interior is authorized to grant rights-of-way for roads, ditches, pipelines, tunnels, and other transportation facilities on public lands under Title V of The Federal Land Policy and Management Act of 1976 (FLPMA).⁹² Under the same authority, rights-of-way may be granted for reservoirs; storage and terminal facilities in connection with systems for the transportation or distribution of liquids and gases (other than water and oil and natural gas); facilities for the storage of materials in connection with pipelines, slurry, and emulsion systems; conveyor belts for transportation and distribution of solid materials; power distribution facilities; and radio communications facilities.⁹³ Of particular importance to mining operations are rights-of-way for reservoir facilities, power distribution facilities, and facilities for the storage of materials in connection with conveyor belts.

BLM regulations under this authority are set forth in Group 2800, of Title 43, Code of Federal Regulations. The regulations refer to a right-of-way grant, which is an instrument formally authorizing the use of a right-of-way over, upon, under or through public lands for construction, operation, maintenance, and termination of a project, and to a temporary use permit, which is an irrevocable, nonpossessionary,

nonexclusive privilege, authorizing temporary use of public lands in connection with construction, operation, maintenance, or termination of the project.⁹⁴ The terms of such grants or permits may range from a month to a year or a term of years to perpetuity, except that the term for a temporary use permit shall not exceed three years.⁹⁵ Terms and conditions are to be established by the authorized officer consistent with the regulations.⁹⁶

Initial contact should be made with the Bureau of Land Management office responsible for management of the affected public lands prior to submitting a formal application. Certain preapplication activities are authorized.⁹⁷ After determining the practical considerations involved in pursuing an application, the applicant files a formal application with the Area Manager, the District Manager, or the State Director having jurisdiction over the affected public land.⁹⁸ Application processing will require an environmental analysis in accordance with the National Environmental Policy Act of 1969.⁹⁹

An important consideration is that the applicant must reimburse the United States for administrative and other costs incurred in processing applications, including preparation of reports and statements pursuant to the National Environmental Policy Act of 1969, before the right-of-way grant or temporary use permit will be issued.¹⁰⁰ These costs must be borne even if the application is denied. Interim payments may be required.

Rental fees are to be paid annually in advance based on the fair market value of the right being granted.¹⁰¹ A bond may be required to assure performance of the permittee's obligations.¹⁰²

Rights-of-Way and Special Use Permits on National Forest Service Lands: The Secretary of Agriculture has elected to establish one set of regulations for the issuance of rights-of-way under Title V of FLPMA, special use permits and leases, and other special use authorizations.¹⁰³ Regulations are contained in Section 251 of Title 36, Code of Federal Regulations. The regulations provide for the granting of easements, leases, permits, and term permits, all of which are described as "special use authorizations."¹⁰⁴

The regulations suggest that informal discussions be held prior to the filing of a formal application in order to identify problems and to advise the potential applicant of what lies ahead if an application is pursued.¹⁰⁵

Applications are filed with the District Ranger or Forest Supervisor having jurisdiction over affected land except in certain circumstances, such as where the lands are under the jurisdiction of more than one agency or more than one unit of the Forest Service.¹⁰⁶ In addition to describing the project in substantial detail, the application must include proposed measures and plans for the protection and rehabilitation of the environment during construction, operation, maintenance, and termination of the project.¹⁰⁷ Additional information may be required by the authorized officer.

Whether an application will be approved, and if so, under what conditions, is largely left to the discretion of the authorized officer. For example, an application may be denied if the authorized officer determines that the proposed use would be incompatible with the purposes for which the lands are managed or if the proposed use would "not be in the public interest."¹⁰⁸

The regulations establish standard terms and conditions that are applicable to any special use authorization, most of which are elaborations of the general requirement that measures will be taken to protect the environment and promote safety.¹⁰⁹

If approved, a term will be established which is to be no longer than is necessary to accomplish the purpose of the authorization and is reasonable in light of all circumstances important to the federal land manager. Authorizations exceeding 30 years will provide for revisions of terms and conditions at specified intervals.¹¹⁰

Prior to construction of facilities under the special use authorization, the holder must submit plans of all developments within the authorized area for review and approval.¹¹¹ Authorization for construction may be conditioned on furnishing a bond or other security to assure that the holder's commitments will be honored.¹¹²

Rental fees are established by the authorized officer based on the fair market value of the rights and privileges authorized as determined by appraisal or other sound business management principles.¹¹³

The Forest Service Special Use Authorization regulations currently contain no provisions for cost reimbursement.

Purchase of BLM Lands: Purchases may be made of public lands (except lands in the National Wilderness Preservation System, National Wild and Scenic River System, and National System of Trails), if the land is not suitable for federal management, if it was acquired for a specific purpose that is no longer valid, or if disposal will serve important public objectives including expansion of communities and economic development which cannot be achieved prudently or feasibly on other public land and which outweigh other public objectives and values.¹¹⁴ An opportunity for congressional action is required if tracts are sold in excess of 1012 ha (2,500 acres).¹¹⁵ Regulations under the statute are in Part 2710 of Title 43, Code of Federal Regulations.

Although this procedure may seem attractive initially as a method for acquiring rights to federal lands, it is actually of limited value. The thrust of the statute and regulations is to require that the lands for sale be identified primarily through the agency land planning process rather than through requests of applicants. Although expressions of interest can be made, public lands are offered only on the initiative of the Bureau of Land Management after they are determined to be suitable for sale.¹¹⁶

If a sale is to be made, it is through competitive bidding procedures. The process is initiated by the publication of a Notice of Realty Action offering the land for sale.¹¹⁷

Minerals on any lands sold pursuant to these procedures are to be reserved to the United States.¹¹⁸

STATE LANDS

State lands are much like federal lands with regard to acquisition and exercise of mine-related land use rights except that with few exceptions mineral rights are available only through the leasing method. Rights to use the surface of leased lands will depend on rights granted under the lease instrument, applicable regulations, and advance review and approval of mine plans by the state land agency.

State lands, like federal lands, are often patented with reservations of minerals to the state. Reference must be made to the applicable statutes and regulations, and to the case law of the particular state in question, to determine the rights of the mineral lessee from the state vis-a-vis the surface owners.

All states have procedures for the acquisition of rights to state lands, usually in the form of leases, permits or rights-of-way. Some state land agencies have authority to effect land exchanges and most have power to sell state lands under certain circumstances.

FEE LANDS

Introduction

This part discusses the rights of a mineral owner or lessee to make use of the surface of a tract of land for the conduct of mine-related activities where neither the surface nor minerals are owned by a governmental entity. Such *fee lands* include patented mining claims. The discussion focuses on the most common situation where the mine operator is a lessee, either of a lessor who owns both surface and minerals, or of a lessor who owns only the minerals subject to surface ownership by a third party. Surface uses may be related to mining just on the tract in question, or to mining being conducted wholly or partially on other lands.

Surface Owned by Lessor

Where a lease is involved, reference is made in the first instance to the contractual document to see what agreement, if any, was made by the parties relative to use of the leased lands for the conduct of mining operations. Although a mineral lessee has broad implied rights to make use of the surface, as is discussed in more detail below, the parties can limit, expand, or condition those rights by contract.

Even where broad surface use rights are granted, the lessee may still be subject to a limitation imposed by law to exercise those rights in a manner that is not excessive. The reasonableness of the proposed use can be determined in part on the basis of whether the lessee has alternative methods to accomplish the intended purpose which will have a more limited adverse effect on the lessor's surface operations.¹¹⁹

In general, where the operations are conducted in a reasonable fashion without negligence, and without contravention of the terms of the lease, there will be no liability on the part of a mineral lessee for surface damages.¹²⁰ Parties to a mineral lease can, and often do, however, provide for the payment of surface damages in accordance with procedures that would be appropriate to a separate surface use agreement such as is discussed later in this section.

A more difficult situation is presented where the lease is silent as to the particular use that the mine operator desires to make of the leased land. A lessee is generally recognized as having the right to make all use of the leased land that is reasonably incident to the extraction of minerals therefrom, which rights extend to making reasonable use of the surface or dumping waste.¹²¹ Whether certain uses not inherently a part of the mining operation, such as employee housing, are reasonably necessary to the conduct of the operation, is a matter not necessarily free of doubt and will have to be determined on a case-by-case basis.¹²²

Of particular concern to a surface mine operator, however, is whether, in the absence of a specific grant, the implied leasehold rights include the right to destroy the surface through the utilization of surface mining methods. As a general rule, a grant of mineral rights will also carry with it the right to extract the minerals through the use of such mining methods as are reasonably necessary. Specific circumstances around a given lease, however, may raise a question as to whether the parties contemplated possible destruction of the surface through the use of surface mining methods.¹²³

Surface Not Owned by Lessor

A far more difficult situation exists where the surface of the land to be mined is not owned by the mineral lessor or mineral owner. Although the same general rules discussed above apply with regard to express and implied rights to make use of the surface, they are applied more strictly where

a third party who does not have an economic interest in the mining operation is involved.¹²⁴

In general, reference must again be made to the instrument wherein the original severance of the surface and mineral estates was accomplished to see to what extent the surface use rights were granted, limited, or conditioned. Since the parties were often not contemplating a mining operation when the severance occurred, there is far less likelihood that such specificity will exist as that found in a typical mining lease. Accordingly, the implied rights of surface use become vital.

In general, the mineral estate is considered to be dominant over the surface estate.¹²⁵ Thus, the mineral owner or lessee has the right to use as much surface as is reasonably necessary to have access to and to carry out the extraction of minerals. This includes rights of egress and ingress. The mineral owner or lessee continues to have the right to realize the benefits from the development of the mineral estate so long as the activities do not unreasonably interfere with the rights of the surface owner.¹²⁶

The principal difference between this situation and the mining lease situation relates to whether the implied rights include the right to destroy the surface in the conduct of the mining operation. The best that can be said in this regard is that existence of the right to destroy the surface will depend on the intention of the parties when the severance was accomplished. Since generally that intent cannot be determined by an examination of the operative legal document, resolution of the question is subject to the vagaries of the law of the jurisdiction involved and the circumstances surrounding a particular situation.¹²⁷

The implied rights of a mineral owner or lessee to make use of the surface owned by another may also be limited by statute. Several states have enacted surface owner protection legislation that requires consent of the surface owner to mining activities.¹²⁸

Use in Connection with Mining on Other Lands

In general, neither a mineral lessee or mineral owner may make use of the surface of a tract of land in aid of mining operations on other lands.¹²⁹ Rarely does an instrument that severs the surface estate from the mineral estate provide for use of the severed surface in aid of mining operations on other lands. It is not unusual, however, to find that a grant of such rights has been made in a mining lease.¹³⁰ The granting clause may, for example, extend the right to make use of the surface in connection with mining on the leased or "other lands." Alternatively, the rights may be granted separately in a specific provision. Although such provisions are enforceable, they are much more likely to stand up against judicial scrutiny if the landowner was aware that he was granting such broad rights in the lease and if he is to be paid separately for uses unrelated to mining from the lands in question.

SURFACE USE AGREEMENTS

A separate surface use agreement may be necessary to acquire rights to use fee lands outside of the immediate area where mining will take place. Also, where there has been a severance of surface and minerals in a tract to be mined, the potential of disputes with the surface owners will generally justify a separate surface use agreement notwithstanding the right of the mineral owner to make reasonable use of the surface. In some states the implied rights of surface use have been severely limited by surface owner consent requirements. Moreover, even where surface use rights have been referenced

in a mining lease, it may still be necessary to obtain an additional agreement to avoid controversy where the surface use rights are not spelled out with sufficient clarity or are not supported by reasonable consideration. This is especially true where mining is going to take place on a tract of land that is being used for other purposes.

Obviously, the length and content of a surface use agreement will be determined largely by the existing circumstances at the site. Nevertheless, there are certain general guidelines that can be followed to ensure the acquisition of adequate rights and to promote a harmonious relationship between the landowner and the mineral operator. In general, in areas where the land is being used for other purposes by the surface owner, an effort should be made to allow those uses to continue to the extent they are compatible with the mine related uses, and there should be full and fair compensation to the landowner on the basis of the degree of mine related use that is made. The mine operator must have the right to make use of the land as needed, but as always, the byword for the successful assertion of those rights is reasonableness.

Following are brief discussions of basic provisions in a surface use and access agreement.

1. Grant of rights: The grant of rights should be extremely broad, but as specific as possible with respect to uses that are contemplated. Use of the tract of land in question for mining purposes should be permitted in connection with mining on that land and on other lands developed by the operator in an area within a specified distance from the tract in question. If appropriate, the agreement should recite that it constitutes consent of the surface owner in lieu of a bond or undertaking required under the provisions of the Stock-Raising Homestead Act.

The rights granted generally should be those "reasonably required or convenient" to the mining operator for the conduct of its operations with a listing of what specific uses might be included. For example, as to a surface mine the rights granted should include the right to construct, install, maintain, and operate stockpiles, waste dumps, tailings impoundments, leach piles, ponds, pipelines, and related facilities. There should be a right to destroy the surface if the land might be included within the dimensions of an openpit or strip mine or might be covered by dumps.

There should also be a provision granting the operator the right to use the land for ingress and egress required or convenient to the grantee for construction, maintenance, and use of linear facilities such as roads, conveyor belts, power lines, and pipelines.

2. Term: The rights granted should be for a fixed period consistent with the proposed or possible life of the mine, and so long thereafter as the operations continue.

3. Multiple Use: So as to minimize adverse effects on the landowner's property and to permit multiple use to the degree possible, there should be fairly detailed provisions concerning the giving of advance notice of proposed operations, maintaining fences, gates, and cattle guards, preventing access by livestock into operational areas or to contaminated water, and limitations of recreational use by employees. Access by the landowner to areas of the property that are not being used in connection with the mining operation should be insured.

4. Reclamation: Where reclamation is possible, the mine operator should have the obligation to do so. The operator may reasonably be required to post a reclamation bond to insure that the reclamation is performed.

5. Indemnification: There should be an obligation on the part of the operator to indemnify and hold the landowner

harmless in respect of any liability that is incurred by reason of the operator's activities. Conversely, if the landowner is to conduct active operations on the affected ground, it is appropriate to request that the indemnification obligation be reciprocal.

6. Compensation: Compensation can take a variety of forms. Generally, there is an initial payment in the nature of a bonus or first year's rental. Simply by reason of the burden placed on the land by the grantor's rights, it may be appropriate, especially if the land is not part of the mineralized area, to pay an annual fee in the nature of a rental. Where a pipeline, roadway, or other linear use is made by the operator, payment can be established on the basis of the overall length of that right-of-way subject to maximum width limitations.

Where the nature of the mine related use causes the land to be unavailable for use by the landowner, a higher rental value per acre affected is appropriate. If the land is not reclaimable, then full value should be paid at a preestablished price or at a price determined by appraisal. Repair or replacement value is appropriate for any damage or destruction to livestock, water rights, or physical features on the property.

The mine operator always would like to have the right to acquire title and exclusive control over portions of the land that would be the subject of substantial investment. This is usually accomplished through an option to purchase title to such areas. The landowner might require that the entire tract be purchased in such event because of the diminution of value that may be experienced as to the remainder of the land. If a price is not negotiated, it can be established by appraisal either at fair market value or at some preagreed increment in excess of fair market value.

In some instances, either because of the insistence of a landowner with negotiating leverage, or because it is in the best interest of the parties, a royalty will be paid to the surface owner. Such royalties can be in the form of a wheelage fee based on volume of material removed from or across the tract in question, or if mining is performed on the tract in question, in the form of a net return from sales royalty. As a rule, royalties are to be avoided because they are more in the nature of tribute rather than fair compensation for reasonable surface use.

7. Taxes: Most agreements provide that the landowner will continue to pay ad valorem property taxes except those attributable to the operations of the grantee.

8. Default: There should always be a default provision allowing notice of default and an opportunity to cure.

9. Assignment: Care should be taken to insure that the rights granted under the agreement remain in effect even though the landowner makes an assignment of his ownership rights. Since the whole purpose of the agreement was to avoid disputes by providing compensation for surface damage, it is appropriate to require that the right to receive payment run with ownership of the land. Because of the importance to the owner of the reputation and financial substance of the mine operator, the landowner might require that he have the right to consent to any assignment by the operator subject to limitations of reasonableness.

10. Surrender: The operator will generally want the opportunity to surrender the property at any time either in whole or in part. The landowner may, however, require that a release be an all or nothing situation. Upon termination, the operator should have the obligation to remove all facilities and reclaim the ground where reclamation is feasible.

ACQUISITION OF RIGHTS BY CONDEMNATION

As a method of last resort when negotiations fail, a mine operator can consider acquiring rights to privately held lands by condemnation. Lands held by a governmental entity generally cannot be acquired through condemnation.

The theory of eminent domain, or condemnation, is that the public interest is served by allowing a procedure whereby interests in land, or title itself to the land, can be taken by the state where necessary so long as due process procedural rights are followed and just compensation is paid. It has been recognized that the rights of the sovereign states to exercise condemnation rights can be provided as well to private institutions whose activities are determined to equate to the public interest.¹³¹ Mining, which occupied such a central part in the initial economic development of various states, has been determined in some instances, particularly in the Rocky Mountain states, to be an activity that is in the public interest.¹³²

Condemnation, however, is not a panacea. Certain realities must be weighed before a determination is made to go that route. Even in the best of circumstances, one can face a lengthy and expensive legal proceeding, the adverse impacts of which might outweigh the benefit that is derived. Because of the vagaries of the law, final success might not be assured.

In deciding whether condemnation rights are available, state statutes must be examined to determine whether the state involved has granted eminent domain powers to mining companies to acquire property for mine related uses. In this regard, the statute might contemplate that any exercise of eminent domain procedures for such things as access rights to a parcel of land be made by the owner of that parcel of land, rather than by a lessee.¹³³ Since in many instances the mine operator will be a lessee, that uncertainty alone might limit the usefulness of the condemnation procedure.

In states where a private right of eminent domain is recognized but specific public uses are not enumerated, it will be necessary to determine whether the use to be made of the acquired land will be a public use.¹³⁴ This may be determined by such considerations as whether the public at large will be permitted to use the land, such as an access road, or whether, as several courts in the Rocky Mountain states have determined, that public use is shown if the public will benefit from the use indirectly by reason of the economic contribution of the mining operation involved.¹³⁵

If the use is authorized, then a showing must be made that there is a *necessity* for acquisition of the property rights being sought.¹³⁶ These rights will usually be for easements for such things as access roads, tailings disposal sites, tunnel rights, or dumpsites for mining wastes. Where alternatives are available, the showing of necessity may be more difficult, but deference is given to the judgment of the mining operator as to the importance of a particular selected plan. Further, the showing of absolute necessity is not generally required, as it is sufficient to show that there is a reasonable necessity for the proposed use.¹³⁷

Procedurally, it can be critical to the mine operator that immediate occupancy is acquired even though the question of damages is left for determination through a more lengthy proceeding. Some states have a procedure for such immediate occupancy.¹³⁸ Obviously, before that occupancy can be achieved, a showing must be made that the criteria discussed above are clearly satisfied. Equally obvious is that there could be a lengthy trial-type proceeding just to establish the right of immediate occupancy.

Once the right to condemn is determined, then a determination of damages must be made. Most states allow an award based on the value of the land or the interest acquired for its "highest and best use."¹³⁹ From the standpoint of the mining company, that value might not have been reflected in the earlier negotiations which were more keyed to the mining company perspective. The determination of the *fair market value* can be a lengthy process with no assurance that the company will end up in a better position than it would have had it simply raised the original price.

PERMITS

Introduction

Numerous permits relative to environmental protection are required in connection with a surface mining operation. Procedures for acquiring such permits are described in Chapter 1 of *Environmental Considerations*, entitled "Environmental Laws and Regulations Applicable to Mining Operations," in the *Underground Mining Methods Handbook*, published in 1982 by the Society of Mining Engineers of AIME.

Permitting requirements of most significance to a surface mining operation are those that relate to surface protection and reclamation. This part describes mined land protection regulations applicable to mining operations conducted on mining claims on BLM and Forest Service administered lands. These regulations, although unique to the particular category of lands involved, are typical in their structure to surface protection legislation adopted by many states.

BLM Surface Management Regulations

Regulations were adopted by the BLM in 1980 that provide for the protection of surface resources on certain unpatented mining claims from the adverse effects of mining operations. The regulations are contained in Subpart 3809 of Title 43, Code of Federal Regulations. They are not applicable to lands in the National Park System, National Forest System, National Wildlife Refuge System, acquired lands, Stock-Raising Homestead lands, land where the surface has been patented by the United States, or lands under wilderness review and administered by the Bureau of Land Management.¹⁴⁰ Thus, as a general rule, there will be a question whether the regulations are applicable in any situation where the lands are subject to intense management regulations. In such instances, there will be special requirements and special rules governing the conduct of mining operations.

The essential purpose of the regulations is to prevent "unnecessary or undue degradation of federal lands which may result from operations authorized by the mining laws."¹⁴¹ Since the regulations effect a new policy of regulating the conduct of mining operations on unpatented claims in contrast to over 100 years of a basic hands-off policy, they lack the stringency of other federal and state regulatory requirements and they reflect recognition of some of the practical aspects of the conduct of exploration and mining operations on unpatented claims.

In general, the regulations place a self-policing responsibility on the operator when disturbance is minor but they insure conscientiousness as to surface protection by requiring notification to the BLM of such activities. The agency is directly involved in approving plans for major disturbances.

The regulations impose a litany of requirements that should be part of any responsible mining operation, and they provide an example of procedures that must be followed under almost all surface protection and reclamation laws.

It is recognized that the burdens of administering a permit procedure for activities of minor impact would be burdensome and generally unnecessary. Accordingly, a category of activities referred to as *casual use* has been defined. Persons engaging in such activities are responsible only for insuring that the operations will not create unnecessary or undue degradation of the federal lands and for compliance with all pertinent federal and state laws.¹⁴² This means that no notice need be given to the BLM of casual use operations, but the operator must nevertheless conduct the operation in such a manner that surface disturbance shall not be greater than that which would normally result from a prudent operation of similar character, and the operator must initiate and complete reasonable mitigation measures including reclamation of disturbed areas.¹⁴³ Also, there must be compliance with federal laws pertaining to air quality, water quality, solid waste disposal, protection of fish, wildlife, and plant habitat, protection of cultural and paleontological resources, and protection of survey monuments.¹⁴⁴ With regard to a surface mining operation, the casual use category would be of most significance during conduct of exploration or development drilling operations.

If the proposed operation will cause a cumulative surface disturbance of 2.02 ha (5 acres) or less during any calendar year, the operator must notify the authorized officer at the District Office of the Bureau of Land Management at least 15 days before commencing operations.¹⁴⁵ Operations include all activities carried out in connection with prospecting, discovery and assessment work, development, extraction, and prospecting of mineral deposits locatable under the mining laws and all uses reasonably incident thereto whether on a mining claim or not.¹⁴⁶ This includes access roads, transmission lines, pipelines, and other means of access for support facilities across federal lands in the vicinity of the unpatented claims.

The notice must contain information about the identity of the operator, a statement describing the activities that will be conducted, and a statement that reclamation will be completed and reasonable measures taken to prevent unnecessary or undue degradation of federal land as required by the regulations.¹⁴⁷ There are also certain standards governing the conduct of activities carried out under a notice relating to the width of access routes, disposal of tailings, dumps, and other waste produced by the operation and the conduct of reclamation.¹⁴⁸ Disturbed land must be reclaimed to the extent necessary to prevent erosion, landslides, and contaminated runoff.¹⁴⁹

No approval is required for a notice filed pursuant to this requirement; however, the operation is subject to inspection by BLM representatives to insure compliance with regulatory requirements.¹⁵⁰ Further, the BLM must be notified when reclamation has been completed so that an inspection can be made to determine its adequacy.¹⁵¹

Of most interest to the operator of a surface mine is the requirement that operations be preceded by submission and approval of a plan of operations where the disturbance level will exceed 2.02 ha (5 acres) per annum.¹⁵² Such a plan will also be required in special areas such as areas designated as a part of the National Wilderness Preservation System and administered by the Bureau of Land Management, areas withdrawn from operation of the mining laws in which valid existing rights are being exercised, and designated areas of critical environmental concern.¹⁵³

The contents of the plan of operation, which dwell on the nature of the operation and the surface protection and

reclamation procedures that will be followed, are established in the regulations.¹⁵⁴ Required time periods for review are established, which allow only 30 days for the initial review subject to discretionary extensions of up to 60 days upon notice to the applicant, but the time involved can be extended if the application is returned for additional information or if an environmental impact statement is required under the National Environmental Policy Act.¹⁵⁵ The agency must also make required assessments of cultural resources and of factors important under the National Historic Preservation Act or the Endangered Species Act.¹⁵⁶

In any major operation to be conducted on federal lands there is a very high likelihood that an environmental impact statement will be required, greatly extending the time necessary for approval of a plan. In any event, an environmental assessment must be performed by the agency.¹⁵⁷ Approval of a plan can be conditioned upon incorporation by the operator of specific requirements imposed by the agency to prevent degradation and achieve reclamation.¹⁵⁸

Of vital importance to the operator is the requirement that a bond be submitted in an amount specified by the authorized officer to cover the estimated cost of reasonable stabilization and reclamation of the area disturbed.¹⁵⁹

As would be expected, any significant modification of an approved plan triggers a requirement for the submission and approval of a revision to the plan.¹⁶⁰

Both a notice of operations and a plan of operations must specify the location of access routes for operations, and such access roads are subject to requirements for prevention of unnecessary or undue degradation.¹⁶¹ Although access cannot be denied under the regulations, it can be managed through special requirements tailored to the circumstances.

There will be instances when the operation is subject to regulation both under the BLM surface protection laws and state surface mine reclamation laws. The regulations attempt to deal with this by saying that the BLM regulations do not preempt the state laws, and they call for consultation between BLM and state representatives to establish a joint federal/state program for administration and enforcement.¹⁶² Whether such a program is in effect in a particular state or whether there will be possible confusion and duplication are matters that must be addressed on a case-by-case basis.

Since the regulations are not based on any particular statutory mandate, the enforcement mechanisms are limited. When an operator does not comply with the regulations, he can be served with a notice of noncompliance or enjoined from the continuation of the operation by a court order. In addition, if unlawful acts are conducted, the operator may be liable for damages.¹⁶³

Similar regulations have been adopted by the BLM in respect of mining on lands which have been identified for possible inclusion in the Public Wilderness System. Review and approval of a plan of operations is required for any proposed operations which will cause a significant disturbance to the environment.¹⁶⁴

Forest Service Surface Protection Regulations: Any surface mining operations involving unpatented mining claims conducted on National Forest System lands are subject to regulations set forth in Part 252 of Title 36, Code of Federal Regulations.¹⁶⁵ In general, these regulations follow the same format as the BLM regulations discussed earlier.

Basically, any person proposing to conduct operations which might cause disturbance of surface resources must give a notice of intention describing the proposed operation to the District Ranger having jurisdiction over the area in which the operation will be conducted.¹⁶⁶ Operations include

all functions, work, and activities in connection with development, mining, or processing of mineral resources and all uses reasonably incident thereto, including roads and other means of access on land subject to the regulations regardless of whether the operations take place on or off mining claims.¹⁶⁷ If the District Ranger determines that the operations will likely cause significant disturbance to surface resources, the operator must submit a proposed plan of operations.¹⁶⁸ The proposed plan of operations need not be preceded by a notice of intent if it is obvious that significant disturbance will occur. There are limitations to the requirement for submission of a notice of intent or plan of operations, but they will not be relevant in connection with a proposed surface mining operation.

The plan of operations must describe the type of operations proposed and how they would be conducted, the type and standard of existing and proposed roads or access routes, the means of transportation used or to be used, the period during which the proposed activity will take place, and measures to be taken to meet requirements for environmental protection as set forth in the regulations.¹⁶⁹ The environmental protection regulations generally require that adverse environmental impacts on National Forest surface resources be minimized and that federal laws and regulations pertaining to air quality, water quality, and solid waste disposal be complied with.¹⁷⁰ Special requirements are set forth relative to the protection of scenic values, fisheries and wildlife habitat, and roads.¹⁷¹

Central to the function of the regulations is a requirement that upon exhaustion of the mineral deposit or the earliest practical time during operations, or within one year of the conclusion of operations, unless a longer time is allowed by the authorized officer, reclamation of surface disturbed by the operations be performed.¹⁷²

There is no set requirement as to time permitted for a plan of operations to be reviewed. An environmental analysis will be performed in connection with each proposed operating plan and if necessary an environmental impact statement will be prepared.¹⁷³

Once approval is obtained, the operations must proceed in accordance with the plan. Any substantial change in conditions will require a formal modification of the plan.¹⁷⁴

The right of access granted to the holder of mining claims is recognized, but the regulations impose requirements for prior approval and minimization of environmental disturbance resulting from construction and use of access routes.¹⁷⁵

A bond or cash deposit will ordinarily be required in connection with a surface mining operation to insure that reclamation will be performed. The amount of the bond is based on the estimated cost of stabilizing, rehabilitating, and reclaiming the area of operation.¹⁷⁶

Periodic inspections are conducted to insure that the operator is complying with the regulations and plan of operations. Upon failure to comply, a notice of noncompliance is given which if not complied with within 30 days will expose the operator to sanctions.¹⁷⁷

The provisions of the regulations apply as well to wilderness areas within the National Forest System.¹⁷⁸ Operations on wilderness lands are, however, subject to more stringent requirements.

State Mined Land Reclamation Laws

Reference should be made to the laws and regulations of the state involved to see if a mined land protection and reclamation law exists that will be applicable to the contemplated surface mining operation. Many states have such laws.

State mined land protection and reclamation laws usually will follow the same general format. When mine related activity reaches a certain threshold level, usually based on the type of activities or degree of disturbance, a mine plan must be submitted to the regulatory agency for review and approval. The plan must show how environmental protection will be achieved during mining, and how reclamation will be achieved afterward. Standards of performance designed to achieve protection of surface resources and to protect water quality will often exist.

Central to the effective application of any such law is a bonding requirement to secure reclamation obligations. Bonding requirements, although necessary to ensure that the burden of reclamation does not fall on the state, can pose severe practical problems for the mine operator.

If mining is to take place on federal or state lands, concurrent jurisdiction of federal and state regulatory agencies may result in duplication of effort and occasionally inconsistent requirements. Usually such a problem can be worked out through a state federal cooperative agreement or informally through coordinating between state and federal agencies.

Ore Reserve Estimation

Richard A. Bideaux, Editor

3.1 Introduction

RICHARD A. BIDEAUX

HISTORICAL OVERVIEW

The art of ore reserve estimation has been in its period of greatest advance over the last 20 years. The purpose of an ore reserve estimate is to first assist in determining if a property is worth mining, and, if so, to guide its later development. Thus, ore deposit models are the underlying foundation for numerous consequent economic decisions, and the correctness of those decisions will be directly dependent on the accuracy of the ore reserve estimates. It is now possible to produce, for the smallest to largest of deposits, spatially detailed mineral inventories of tonnage and grade or quality, including statistically derived estimates of these values' probable accuracy and precision.

The ability to provide such desirable ore reserve estimates rests on the modern development of improved geological, geometrical, and mathematical techniques of mineral deposit model construction. Most of these improved methods depend in turn on the pervasive use of digital computers that have provided dramatically larger storage capacities and higher speeds at an ever-decreasing cost over this same time period.

Ore reserve estimation is now a suitable topic for a doctoral dissertation in mining engineering. Nevertheless, it remains an art, requiring practice and judgment in its application. Even with the power of present techniques, or those likely to be developed in the future, this must always remain so, due to the inherent geological complexity of mineral deposits. From very limited data, well-considered geological inferences must be drawn, subject to frequent review as new information becomes available.

Any ore reserve estimate must begin with the collection and treatment of the geological samples drawn from and defining the ore body. From the earliest stage at which a preliminary ore reserve estimate can be made, these available samples may represent as little as 10^{-6} to 10^{-8} of the bulk of the mineral deposit penetrated. Even just prior to a production decision only 10^{-5} to 10^{-6} of the deposit may be available for inspection and analysis. The samples available to control ongoing mining may bulk as much as 10^{-3} to 10^{-5} of the material to be mined. Considering the cost of collection and importance of this sample data, on which all further computations rest, accurate information about each sample must be obtained and made readily available for use in any of these cases. Information on their accurate spatial locations and as much of their geological character as might affect later mining decisions should be collected. It is now possible to economically provide virtually unlimited computer storage and processing for this basic data.

The first steps in deposit model construction involve geometrical and geological considerations. For a surface mine, representation of both the preexisting topography and working faces must be incorporated. The deposit's geological features must then be interpreted to the degree necessary both to guide efficient mining and to assist future geological exploration. With computer assistance, this topographical and geological data can presently be captured and stored to almost any degree of detail desirable.

The greatest recent advances in ore reserve estimation have been made in the area of grade or quality computation. First there has been a greater appreciation and usage of ordinary statistics. These methods depend on several assumptions about the nature of the geological samples collected. The ore body is considered to be made up of a total population of all such possible samples that could be taken. The available set of sample data is then representative of the whole deposit to the degree that it has been drawn on a random and unbiased basis from the total population. The individual sample values obtained are considered to be statistically independent or spatially uncorrelated with one another. These sample values from deposits of many metallic and industrial minerals, as well as the calorific content of coal, will often exhibit a symmetrical frequency distribution or grade histogram. Ordinary statistics provide efficient estimators and descriptors of the mean value and dispersion about the mean of such distributions.

Deposits of some other commodities, especially where the material of economic interest is present in quantities little more than that of trace elements, often exhibit a different underlying distribution of values. As examples, these include notably lode gold, silver, and diamond deposits, molybdenum porphyries, roll-front uranium deposits, and also contaminants in coal such as sulfur. Rather than being symmetrical, their grade frequency distributions are asymmetrical, skewed towards a long high-grade tail, and often truncated at low grades. These distributions can usually be transformed to a more symmetrical form by taking logarithms of the individual sample values, leading to their designation as lognormal. Much of the worth of such deposits may be represented by values falling in the high-grade tail of these distributions, so lognormal distributions have received considerable attention in recent years. A body of statistics to deal effectively with such cases has been developed.

The next necessary step in mineral deposit model construction required some method of extension of sample grades throughout the volume of the model. Virtually every method ever used for manual computations in the past has been

programmed for the computer and extensively analyzed as to its characteristics. At their simplest, these include relatively crude methods that regard the deposit essentially as a point value or distribution, such as the general outline method. Somewhat more complex but still straightforward methods build polygonal and triangular models, either in plan or section, where each drill-hole sample value is considered to entirely represent the whole of a geometrical fraction of the deposit, or is simply averaged with at the most a few other samples.

In earlier years, more complex models were built using linear regression or trend-surfaces, sometimes in three dimensions. These have fallen into disfavor, partially because of the complexity of their construction and display, and also because of an inability to objectively determine the number of determining coefficients to be used in the model. With the wide-spread availability of computers necessary for their handling, even more detailed model geometries have been developed, beginning with regular or variable-block three-dimensional models. These were followed by development of models more specialized in their geometries to the types of deposit under examination, such as regularly gridded seam models for coal and other stratabound commodities. The most general type of digital model possible, composed of polyhedra of arbitrary shape and size, has seen little use as yet due to the details of its construction and complexity in its manipulation. However, these models must find use eventually for accurate and efficient evaluation of the most geologically and structurally complex types of deposits. These models might better be able to explicitly represent such complex geological deposits as steeply dipping, anamorphosing metallic veins, the recumbent folds found in some coal deposits, and the geometry and zoning of roll-front uranium deposits.

Along with the computer's ability to handle more detailed geology and geometry in deposit models came more complicated methods of weighting together sample grade values. In general, these consider all samples available within some distance of the center of the block of ground being estimated, with the weighting schemes being an empirical function of distance and sample geometry, usually incorporating observed anisotropisms in the mineralization.

A complete mathematical theory, the methods of which go collectively under the name of geostatistics, has been derived, largely perfected, and accepted over these last two decades. These geostatistical methods are intended to meet many of the problems of mathematical assessment of ore reserves. Compared to the assumptions of ordinary statistics, geostatistics can assess the degree to which nearby sample values are in fact found to be spatially correlated. This information is used in constructing a model of the grades throughout the deposit that is of minimum deviation or a best possible estimate compared to the sample data. The block grades so derived have been found to deviate from assumed values on average by the minimum amount possible.

Further, geostatistics allows the computation of error bounds on the precision of these grade estimates, taking into account the sample variability and geometry, as well as the size of the individual blocks of ground being estimated. The accuracy of the resulting model can be assessed through successive deletion and estimation of the missing value of the actual samples.

A principal tool of geostatistics, the variogram, allows definition of the spatial correlation or continuity of mineralization. Variograms thus quantify the concept of distance of influence of individual samples and permit study of the

irreducible error in sampling of a deposit. They provide derivation of an optimum function with which to combine sample values to obtain estimates of the grade of intervening blocks of ground, and the associated error of estimate. Knowledge of the variogram also permits prediction of the location and additional number of samples necessary to reduce the error bounds on an ore reserve estimate to any predefined level.

By geostatistically deriving the expected frequency distributions of material expected to be encountered in a mining block, more accurate estimates of overall recoverable ore can result. Grade-tonnage curves obtained from this data have been found to be quite accurate, and explain why many operating mines had to derive empirical adjustment factors in the past.

COMPUTING EQUIPMENT

A consensus on the complement of presently available computing equipment desirable for ore reserve analysis seems to have been reached. Components that should be directly available to a user include a terminal, usually with graphics capability, a coordinate digitizer, and hard-copy plotter. Many choices are possible for each of these functional components. Digitizers are used to capture drill-hole locations, surface topography, and geological outlines. The (x, y) position of the digitizer, while being moved over property maps, is converted to the deposit model coordinate system either on a point-by-point or continuous basis. Accuracy of the digitized data can be quickly and cheaply checked by display on the terminal, or converted to hard copy by the plotter. Computed data, often shown by means of contoured maps, can also be displayed and plotted.

Some remarks on the computer and its data storage capabilities can also be made, presuming there is some choice in its selection—often quite large and capable corporate machines are already available, with which the data terminal is used to communicate. Care must be taken to insure that the computer has sufficient precision in its internal representation of decimal numbers to not create a significant loss of accuracy in extended calculations. The representation of the coordinate system chosen for the deposit can sometimes exceed this limit; a possible solution is to translate the deposit by subtraction of constants from all coordinates, to maintain numerical significance of the least significant digits. Alternatively, it may be necessary to make some computations in double-precision mode.

Using block models as a reference, an average model size for a deposit to be mined by large-scale surface methods is perhaps $100 \times 100 \times 50$ or 500,000 blocks. Depending on detail or the amount of data associated with each block, such a model may then occupy 2 to 10 megabytes of storage (or as little as 0.2 to 2 megabytes if data storage compression techniques are used). Such models are best handled in sequentially accessed parts, either a horizontal or vertical section brought into the computer's main memory at one time. A section through such a model may require 20 to 200 kilobytes, with perhaps double that central memory necessary for the computer program and its ancillary data. The largest models may be in the range of several million blocks; here data compression is a necessity to keep the model storage within available capacity.

Close attention must be paid to backups of the sample data and models at various stages of construction. Double backups are advised for critical and expensive-to-replace data. Backed up files should be printed, mapped, or otherwise operated on to verify that they are correctly made and usable.

IMPLICIT MODELS

Manual computation of ore reserves is still quite appropriate for smaller properties and for larger properties that are either geologically quite simple or too complex for computer modeling! Reserves for an ore body that is quite homogeneous and with reliable continuity can be fairly easily maintained by entirely manual methods, even if the property is of large size—an example might be a limestone quarrying operation for a cement plant. A computerized ore body model is not entirely necessary since mine plans relying on selective mining are not necessary to be implemented. Powerful desk top calculators are of great assistance, and digitizers with microcomputer processors can be used solely as digital planimeters.

At the other end of the spectrum, the most complex ore bodies can be so discontinuous and unpredictable in their mineralization that an explicit computer model can be very difficult to construct and of little reliability. Highly faulted phosphate rock or barite deposits and lensed kaolin deposits might be some examples here. The partial geological interpretation given by the mine geologist to drill-hole results shown on cross section are the only reasonable basis for mine planning.

It should be noted, however, that a computer-based statistical model of such types of deposits can be of considerable help in predicting production from deposits of discontinuous or difficult-to-localize mineralization. While an explicit model cannot be constructed, averages, distributions, and trends of mineralization can be analyzed and used as a basis for meeting production requirements. The desired quantity of mineral may not be exactly located and able to be produced in the very short-term, but in the medium- to long-term, expected production can often be predicted quite successfully. Other examples of deposits to which such models have been applied are placer tin, gold, and alluvial diamonds and also large and geologically complex uranium deposits.

DRILL-HOLE DATABASES

The computer is of great assistance in helping to organize and maintain large drill-hole data files. It can be called on when there are as few as several tens of holes, and becomes a virtual necessity as the number of drill holes reaches into the thousands, or in a few cases, tens of thousands, and the sample intervals into perhaps hundreds of thousands. (Grab or bulk samples can be treated as drill holes at a point, while channel samples can be stored as short drill holes.)

Construction of such a drill-hole data base, even prior to its use, can be a major geological and data processing task. Some man years of effort can go into collecting the data and entering it into the computer. Required is the ability to store, for each drill-hole, a unique identifier, perhaps information on the drilling contractor, collar location coordinates, and down-the-hole survey data. Collection of this last is often underemphasized, yet has proven to be of substantial value in most cases. Obviously, lack of knowledge of reasonable exact locations of samples taken from the drill-hole can be a contributing source of error in later ore reserve estimates. There are cases known where unsurveyed holes, thought to be vertical, have returned to the surface; and ore bodies thought to be drilled out, have been entirely missed by the intended main haulage shaft.

The results of geological and chemical examinations of the samples are then added to the files containing the geometrical parameters of each drill hole. Generally, at least until a preliminary understanding of the most important data

is gained, any decisions should be on the side of storing too much data. Too early a censoring or prejudgment of what may be important can, unfortunately, lead to relogging of the samples. It is relatively easy to add all captured information initially, but quite expensive to later add further data to the files. One of the most common errors concerning bedded deposits, such as coal, is for the geologist to decide an interval is not of economic thickness and thus omit logging it. While this judgment as to minability may be entirely correct, the overall correlation of that bed may be essential in controlling the construction of a model of the deposit, particularly for beds that pinch and swell over their extent. Missing data values should be explicitly coded, recognized, and appropriately treated in further processing.

All engineering decisions should be deferred to as late a stage in data collection and model construction as possible. The main utility in using computer-resident data is in the ability to quickly reevaluate with different engineering parameters, so the data should exhibit the full range of values seen in the real-world deposit.

After entry, the sample data base must be verified. The files should be scanned by computer programs designed to catch simple errors and full printed listings visually examined. The drill-hole locations should be plotted in plan view if made from the surface, and ideally a set of cross-section plots made on whichever drill-hole shows at least once. Assay or quality values are conveniently displayed alongside the drill-hole traces.

SAMPLING PROBLEMS

All parties, including geologists, mining engineers, and data analysts, who are assisting or later will be using an ore reserve analysis derived from drill-hole results, bear responsibility to try to detect anomalous or erroneous sampling problems. While various methods to help detect such problems can be programmed for the computer, the variety and subtle nature of some such errors can at present only be recognized by human analysis. Operator biases and equipment miscalibration can often be demonstrated by statistical treatment of replicated analyses, by displaying their differing relative accuracy and precision. More subtle problems may be due to the methods of chemical analysis employed, or sample preparation. An interesting total metal grade may be of no value if it is later found to be locked into a mineral not amenable to recovery in the plant. The analytical methods should be similar to those used in a recovery plant, with determinations based on total sample decomposition rarely appropriate.

It is virtually impossible to take subsamples that are representative of the whole, whether they be the original drill-hole samples or splits thereof. This is due to differential hardness and specific gravity effects; any mechanical process has varying recoveries of the different mineral components depending upon their physical properties. For example, down-the-hole salting effects can sometimes be observed, when a rich but thin metalliferous zone has been penetrated. Such high-grade fines can contaminate deeper samples, or the bottom of the hole.

One of the most difficult effects to detect is bias in the location of the drill holes, violating statistical assumptions of randomness or equiprobable sample locations. These may be due to the drilling crew's unwillingness to collar holes at the intended, but perhaps difficult to occupy, stations when shallower slopes are somehow related to mineralization; or a geologist's unwitting "nose for ore" or even subconscious

desire to "look good"—thereby selectively overdrilling high grade zones.

A somewhat subjective judgment concerns that of continuity and stationarity of the economic components of potential ore-grade material. Geostatistical variograms can provide necessary but not sufficient data bearing on geological continuity of mineralization. There are all too many cases where deposits thought to be well defined by surface drilling have been found to actually consist of discontinuous and hence uneconomic lenses.

A much rarer but very misleading situation can arise in analysis of drilling results from folded bedded deposits. It is necessary to have drill-hole penetrations at more than twice the frequency of the periodicity of folding, otherwise an effect known as aliasing occurs. Underdrilling results in an interpretation of a much lower periodicity and amplitude, or much smoother folding. While the actual tonnage later encountered is greater than anticipated, so will be the mining problems due to unanticipated tighter folding. In one case of a valuable coal deposit that proved eventually to consist of an extraordinarily large number of parallel, flat-lying discrete beds the first company with an option on the property rejected it. This was based on an interpretation that recumbent folds must be present, when in fact that was not the case. An ability to discriminate individual beds on the basis of their trace element chemistry might have assisted a correct determination in this case.

Stationarity of mineralization refers to its similarity over various parts of the deposit. Detection of significant differences in the continuity, anisotropy, or grade distribution over different parts of a deposit should be sought and, if detected, submodels must be constructed.

Perhaps the highest level of ore reserve analysis is to recognize that the available data is insufficient to make an ore reserve estimate that will have a high enough degree of confidence to justify further investment in the deposit. In such cases, usually a statement can be made as to the additional amount of information that it appears necessary to acquire, whether by using ordinary statistics or geostatistics. The drilling results obtained to the present can be analyzed, and the best apparent locations for obtaining further data can be indicated. Their locations can be optimized to give a maximum reduction of confidence bounds on consequent ore reserve estimates. If the expenditure necessary to acquire this information is greater than the return on its value, the property should be abandoned. Deposits of some minerals can present almost insurmountable estimation problems. Their inherent variability is so great that they would almost have to be mined by sampling to bring the accuracy of ore reserve estimates within the bounds to prudently justify investment. Nevertheless, many such deposits are in fact profitable.

Density determinations present another set of problems. Accurate and precise densities are a necessity, since their use in tonnage factors is one of the largest components of error in overall tonnage estimates. If density determinations are made on drill core samples, multiple determinations are necessary. Removal and weighing of a bulk sample, with its density determined by measurement of the volume of the excavation, is an excellent method.

If densities are available, for example, to only three digits of numerical significance, that is also the maximum number of significant figures to which any reserve tonnages can be reported. Gross errors in density determinations, such as using values obtained from the other mines in a district, have led to seriously overestimating actually obtained recoveries. For deposits of materials of especially high or low density,

such as iron ores or borates, it will be necessary to derive and use a function of assay grades to compute expected densities and tonnages for the individual parts of a model.

SURFACE TOPOGRAPHY

Surface topography is another type of information that it is necessary to obtain quantitatively for an ore reserve estimation of a property to be mined from the surface, almost regardless of the type of model or the methods used in its construction. This is formally a digital terrain model, of interest in many areas besides mining, such as geography, geomorphology, forestry, military, etc. Again, the adequate definition of surface topography can be somewhat of an art, as interpolation of the data is usually required. Some presently available methods can produce such surface models entirely automatically from stereographic aerial photographs, or by digital stereoplotter operator interpretation. The more usual method is by preparation of an intermediate contour map at a vertical resolution appropriate to the surface roughness; then these contours can be digitized in continuous mode and the resulting (x,y,z) triplets interpolated to assign elevations on the desired planar grid. In terms of reliability and ease of producing the desired data, manual digitization of elevations at the intersections or centers of an appropriate grid overlay, followed by manual computer entry, is quite feasible for properties of up to intermediate size. The selection of digitization resolution can require some judgment; steep surface topography requires relatively finer resolution, and a balance must be made between adequate representation of the surface features vs. the corresponding resolution imposed on the underlying volume, since too fine a surface resolution can result in an unwieldy ore deposit model.

The representation of surface topography by such digitization can be a later source of controversy. Accuracy of the quantized representation should be checked first by computer programs designed to find gross errors (that are always present), then by a plotted contour map for final verification by overlay on the source map. Due to the quantization of the topography, this check plot will never exactly overlay the (essentially analog) source map, with quantization effects most apparent as departures from smoothness along ridge lines and valleys. However, the errors introduced are more apparent than real; plotted cross sections of the source and quantized data, without vertical exaggeration, will usually show a negligible departure between the two sets of data. For most types of computer models, it should be realized that the elevations at grid points will be treated further as horizontal flat planes with step boundaries between adjacent plates. Again, comparatively little error in subsequent volume calculations is usually involved, with counterbalancing errors, so that errors introduced into later tonnage figures can be ignored for practical purposes.

GEOLOGY

A geometrical model of the subsurface geology should first be constructed and checked, before grades or qualities are derived. Only after it has been verified and accepted should modeling of grade or quality attributes begin. Based on those geological units that are mappable, the deposit geology should be interpreted and transferred onto plan and/or section maps. The units chosen are usually able to be visually distinguished by a geologist, but for some highly altered deposits, more detailed petrographic work may be needed. If a wide range of recognizable geological units has been logged from the core and carried in to the drill-hole data base, the economic mineralization should be statistically

studied in each coded unit. This can aid the geologist and ore reserve analyst in determining which units have statistically similar mineralization, which can then be considered for combination in the model, and those units that show bi- or multi-modal distributions, indicating that there may be petrological subunits requiring further discrimination.

For most deposits, even those with complex geology, it is rare that there are more than half-a-dozen rock types requiring distinction in their computer models. The overall effort is to make the geological model sufficiently complex to represent reality, but not overly so, requiring extra effort throughout its construction.

Special attention must be paid to the nature and location of contacts between rock types, as these will often be ore-waste boundaries. If faults are present, their relationship to the mineralization must be determined. The geometry of folding in bedded deposits is equally important. The interpretation of deposit geology will ultimately be reflected in tonnages of ore; note that it necessarily involves subjective interpolation and extrapolation from the geology logged on the penetrating drill holes.

Geological boundaries that are interpolated within the limits of drilling will be subject to some errors of location, but these will also be largely counterbalancing, especially when considered in the large. Overextrapolation of units beyond the boundaries of drilling is potentially a source of much more serious problems. Compared to the interior of a model, material around the margin can assume significant volumes within very short extrapolation distances. The most serious ore reserve misestimates have arisen either from geological projection of mineralized material too far outside the bounds of known data, or across fault structures not recognized or thought to be mineralized on both sides. An apparent doubling or more of tonnage can then easily result. In some cases, the subsequent mining feasibility study has been equally in error, forcing the mine to close with near-total loss of the capital investment as the true situation came to be recognized.

Geological outlines can be captured either by digitization, or manual coding onto a grid, in the case of block models. For gridded seam models, the locations of outcrops can be estimated and incorporated, along with burnouts and wash-outs in coal deposits. These digitized outlines should be plotted back to scale and visually checked for accuracy before their inclusion in a model. For block or gridded seam models, it is possible then to interact the geological outlines with the blocks so as to carry fractions of more than one geological unit into each block. For manual coding, these percentages are estimated and loaded directly into the blocks.

While some models with blocks able to be composed of as many as four different rock types have been built, it is rarely actually desirable to hold such detail. It can perhaps be justified if there are unmineralized dikes or sills cross-cutting more important mineralized units, when the dikes are below the limit of resolution of their thickness by whole blocks in the model. While these dikes might be mappable on the surface, their location below the surface is rarely well established.

It is possible today to economically work with quite large models, so that consideration should be given to halving the grid size and staying with only one rock type per block. Experiments made on multiple rock type per block models, converted to only the majority rock type in the same size blocks, indicates only about 1% difference in overall tonnages resulting from the lower spatial resolution. The increased resolution afforded by split blocks may be justified when more

data is available and ore reserves to be based on selective mining are considered.

Once the model geology is loaded, it should be plotted back and visually examined. Both plans, and preferably vertical sections in orthogonal directions, should be made. If the geology has been loaded from sections in only one direction, it will often give a curious and unintended appearance when seen in plans and sections at right angles, perhaps requiring corrections before the geological model is judged acceptable.

For geology that has been explicitly coded into a model, rather than being derived automatically from drilling results, a further cross-check is desirable. The block in which every drill-hole sample is located should be computed, and the match of the geology coded for the sample should be compared with that in the block. Any mismatches must then be noted and reconciled.

Occasionally no geologist can be found willing to try interpretation of complex drilling results, yet an ore reserve estimate must be made. Here an empirical, statistically based model must be resorted to, with the deposit geology interpolated directly from the drill-hole geology. Each block is assigned the rock type of the nearest drill-hole sample. This is the discrete digital equivalent of polygon assignment in two-dimensional plan sections, or a polyhedral assignment in three dimensions. Models made in such fashion should ideally be used only for global reserve assessment, although considerable reliability can be placed on the overall results.

GRADE ASSIGNMENT

Once the geological model is prepared, extension of the grades throughout the model can follow. In the following sections, every method in current use is discussed in considerable detail, so only general remarks will be made here. The selection of a suitable method is controlled by the geological nature of the deposit, as well as being a balance struck between the time, money, expertise, and facilities available to make a model.

As with manual methods, polygonal or triangular models are the most easily constructed, if suitable programs are available. The set of polygons constructed by determining perpendicular bisectors of the lines joining adjacent drill holes is unique. A triangularization of the same data, where triangle edges exist if the polygon sides to which they are perpendicular also exist, is likewise unique, except in cases of exactly square drilling patterns.

These types of models are not able to hold either the geological or grade data with much resolution, however, so their use should be restricted to small deposits, or those that are densely drilled, or fairly uniform in their mineralization. Biases of overdrilling in high-grade material must be particularly watched for in their use, and they are especially susceptible to overestimation of tonnages by unrealistic extrapolation outside the boundaries of known data.

Any type of deposit can theoretically be modelled in a three-dimensional block model, and this type is also the most easily constructed and manipulated on a digital computer. It should always be the first choice of model to be considered, to be rejected only if there are other overriding considerations. Bedded deposits can often be efficiently handled by gridded seam models. By using a partial block strategy, geology can be incorporated into any of these model types if the effort is warranted.

The rock types in the samples must be matched to the same rock type or rock types found to have similar grade distributions in the model for grade estimation. This cannot

be overemphasized—again, uncritical model construction not honoring this principle has in the past resulted in highly inaccurate models, with disastrous consequences to the property owner. In the case of faults cutting off mineralization, it may be necessary to doubly code a petrologically identical rock type on either side of the fault to allow distinction of mineralized and unmineralized equivalents.

It should always be borne in mind that all of the methods of grade assignment throughout a model involve mathematical interpolation and extrapolation that are inherently smoothing processes. As such, they will be found to be more or less accurate in their prediction of grades when the estimated material is actually mined. Polygonal and triangular grade interpolations do not realistically model the probably smoother distributions that will actually be found, but may still prove not too far in error in favorable cases of slowly varying, continuous mineralization. Various entirely empirical interpolation methods such as those using inverse distance will more accurately model rapidly varying grade distributions with a still relatively modest expenditure of computer time. The geostatistical methods undoubtedly can be expected to provide the best estimate of what will ultimately be found, but require considerable knowledge in their application, as well as much larger expenditures of computer time. Nevertheless, they have been growing in popularity and will deservedly continue. With ever faster and cheaper computers and improved computer programs, the consequences of the greater computing time requirements for geostatistical analyses will have decreased impact.

However a grade model is constructed, it must also be extensively verified before much credence is placed on results obtained from it. A thorough and necessary check involves comparison of frequency distributions of mineralization of the various rock types for overall correspondence with the sample distributions from which they were derived. Another sufficient check should also be made of the input sample values individually against the interpolated values. This will help insure that gross errors have not been incorporated into the model, unfortunately all too easy to do even with long-used and well-validated computer programs.

CLASSIFICATION OF ORE RESERVES

In the interest of consistency of presentation, the following section is reproduced verbatim from Readdy, Bolin, and Mathieson, 1982. Their article in SME's companion *Underground Mining Methods Handbook* is also recommended as an overview of ore reserve calculation; while directed to deposits suited to underground mining, most of their discussion applies equally well to deposits minable by surface methods, or a combination of each.

The definition and classification of ore reserves has varied over the period of development of the modern mining industry. *Ore* is generally understood to be any naturally occurring, in-place, mineral aggregate containing one or more valuable constituents that may be recovered at a profit under existing economic conditions. This definition ignores special situations, such as wartime production, or those cases when an otherwise unprofitable deposit may be exploited for political or social reasons.

Ore reserves are classified with respect to the confidence

level of the estimate. Traditionally, ore reserves have been classified as proven (measured), probable (indicated), possible, and inferred. Historically, proven ore has been regarded as that which is "blocked out," i.e., measured, sampled, and assayed on four sides; probable ore as blocked on three sides; possible ore as blocked on two sides; and inferred ore as ore grade material that is known on only one side.

More recently the US Bureau of Mines (USBM) introduced the following ore reserve classifications:

Measured Ore

"Measured ore is ore for which tonnage is computed from dimensions revealed in outcrops, trenches, workings, and drill holes, and for which the grade is computed from the results of detailed sampling. The sites for inspection, sampling, and measurement are so closely spaced and the geologic character is so well defined that the size, shape, and mineral content are well established. The computed tonnage and grade are judged to be accurate within limits that are stated, and no such limit is judged to differ from the computed tonnage or grade by more than 20%."

Indicated Ore

"Indicated ore is ore for which tonnage and grade are computed partly from specific measurements, samples, or production data and partly from projection for a reasonable distance on geologic evidence. The sites available for inspection, sampling, and measurement are too widely or otherwise inappropriately spaced to outline the ore completely or to establish its grade throughout."

Inferred Ore

"Inferred ore is ore for which quantitative estimates are based largely on a broad knowledge of the geologic character of the deposit and for which there are few, if any, samples or measurements. These estimates are based on an assumed continuity or repetition for which there is geologic evidence; this evidence may include comparison with deposits of similar type. Mineral bodies that are completely concealed may be included if there is specific geologic evidence of their presence. Specific estimates of inferred ore usually include a statement of the special limits within which the inferred ore may occur."

If geostatistical methods are used, providing estimation variances for each unit of the model, a probabilistic classification of reserves on a unit basis is then possible. The combined estimation variances of the portions of the reserves larger than individual units still cannot be defined, however. Because of intercorrelations of the data used to derive the grade estimates, a strength of the geostatistical method, the variances of adjacent units are not independent, so cannot be combined as in ordinary statistics. Nevertheless, a good idea of the overall relative precision of the reserves can be gained. In any event, the continuity of the reserves in any category should be examined on maps covering the deposit, as an initial guard against the infeasibility of actual mining.

3.2 Computerized Conventional Ore Reserve Methods

HARVEY P. KNUDSEN

The first use of computers in ore reserve estimation was simply to automate the traditional manual methods of ore reserve estimation. Due to the power and speed of the computer, new estimation techniques became available for the ore reserve analysis (O'Brian, Weiss, 1968). Among these new techniques were automation of the polygonal method, various interpolation techniques based upon inverse distance weighting, and the geostatistical techniques developed in the last 20 years.

This section describes the polygonal method and the distance weighting interpolation methods that are in current use by the mining industry. Geostatistical methods of ore reserve estimation are discussed in the next section. The description of each method in this section includes the method of calculation, the type of model produced, and a discussion of the properties and characteristics of each method.

DESIRABLE PROPERTIES OF ORE RESERVE METHODS

An ore reserve method can be judged on several different criteria, but certainly the main criterion is simply how correct are the estimates. Correctness refers not only to the overall reserve figures, but also to the local block grade estimates that will form the basis of the mine plans. Let Z_1, Z_2, \dots, Z_n be the actual grades of blocks within an ore deposit, and let $Z_1^*, Z_2^*, \dots, Z_n^*$ be the corresponding estimates of the grades made by a particular ore reserve method. Three particularly informative measures of prediction accuracy can be determined by comparing the true grades with the estimated grades. First, we can determine whether the estimator is unbiased by calculating the average error, \bar{E} , as given in:

$$\text{Average error} = \bar{E} = \frac{1}{n} \sum_{i=1}^n (Z_i - Z_i^*)$$

The average error should be very small, and is usually found to be when the comparison is made on all the blocks in the deposit, regardless of cutoff grade. For most mining projects it is very important to determine whether the estimates are unbiased for grade estimates above the cutoff grade. A good estimator should be unbiased for all cutoffs. This second measure is often referred to as the conditional unbiasedness property and can be measured by examining the errors made for block estimates above specified cutoffs.

The third measure of accuracy is the variance of the errors as follows:

$$\sigma_e^2 = \frac{\sum_{i=1}^n [(Z_i - Z_i^*) - \bar{E}]^2}{n - 1}$$

The lower the variance, the better the estimator.

The foregoing three measures of accuracy can only be obtained by direct comparison of predicted grades to actual mined-out grades. In the absence of actual mined-out block grades, a comparison can still be made by comparing estimates of individual drill-hole composites with the actual value of the drill-hole composites. Such comparisons are widely used to validate the ore reserve method chosen for a particular project (Knudsen and Kim, 1978; Readdy, et al.,

1982; Kane, et al., 1982). The methodology is simple: a composite is removed from the data set and an estimate of the removed composite is made from the surrounding data using the particular ore reserve method. The process is repeated many times, usually over all available composites. The measure of accuracy is then calculated for the resulting set of errors.

POLYGONAL METHOD

Two types of ore reserve models can be constructed using computerized versions of the polygonal method. The first model consists of a set of computer calculated polygons with appropriate calculations for tonnage and grade. Fig. 1 shows an example of a computer generated polygonal model of a uranium mine. The second model is a standard block model where the grade assigned to each block in the model is the grade of the nearest drill-hole composite. As can be seen in Fig. 2, such a model is a close approximation of a standard polygonal model. Both models are in current use, although the block model is easier to utilize in subsequent computerized mine planning.

Computer-Drawn Polygon—Traditional Method

A computer program for the polygonal method should do three basic tasks. First, it should define polygons around each drill-hole composite. Second, it should compute the area of the polygon from which the tonnage can be calculated. Third, the program should store the polygon data for later mine planning and ore reserve reporting by either computerized or manual methods.

The first task of defining a polygon around drill holes is not easy to program, but, fortunately, several algorithms and programs have been published. One that works well is the algorithm published by Green and Sibson (1978). Commercial software for the polygonal method is also available.

An Approximate Polygonal Method

Most of the computerized mine planning systems developed for open pits have been based upon the standard block model for the mineralization inventory. Using the polygonal model to assign grades to this block model results in each block being assigned the grade of the nearest assay composite.

Whereas a computer program for the traditional polygon method is difficult to write, the approximate polygonal method is quite easy. The main algorithm of the program consists of calculating the distance from the center of a block to each surrounding assay composite. The grade of the closest assay composite is then assigned to the block. This is illustrated in Fig. 3, where hole AM 148 is found to be closest to the center of the outlined block. This grade assignment is repeated for each block in the model.

Choice of the Maximum Polygon Size

The size of the polygons is directly related to the drill-hole spacing. In areas where the holes are closely spaced, the polygons will be small. Likewise, in areas where the drill holes are far apart, the polygons will be proportionately larger. Usually, however, a limit will be set on the maximum size of the polygons. This limit has been commonly referred to as the maximum range of influence of an assay.

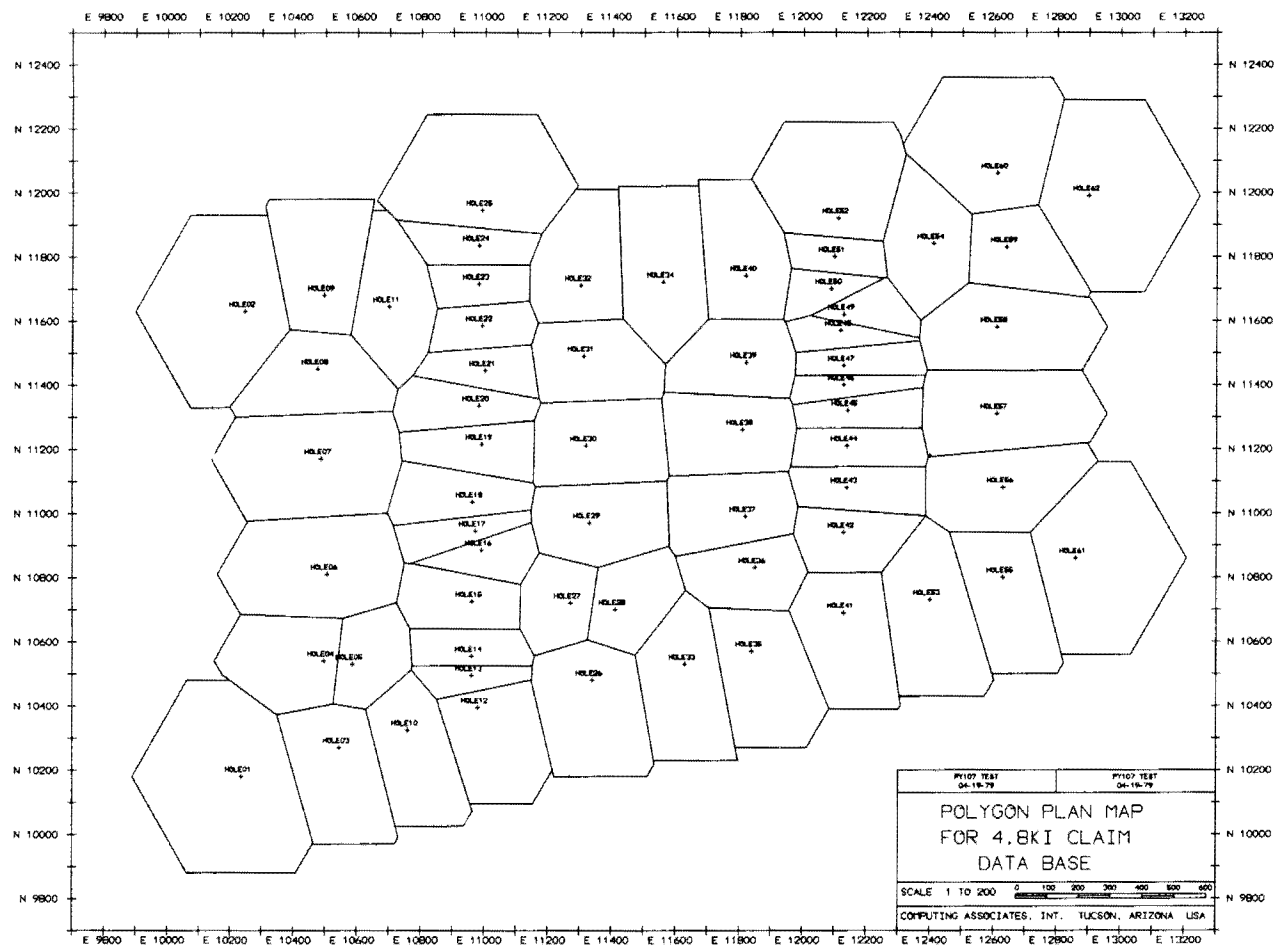

Fig. 1. The polygonal method (courtesy of Control Data Corp.).

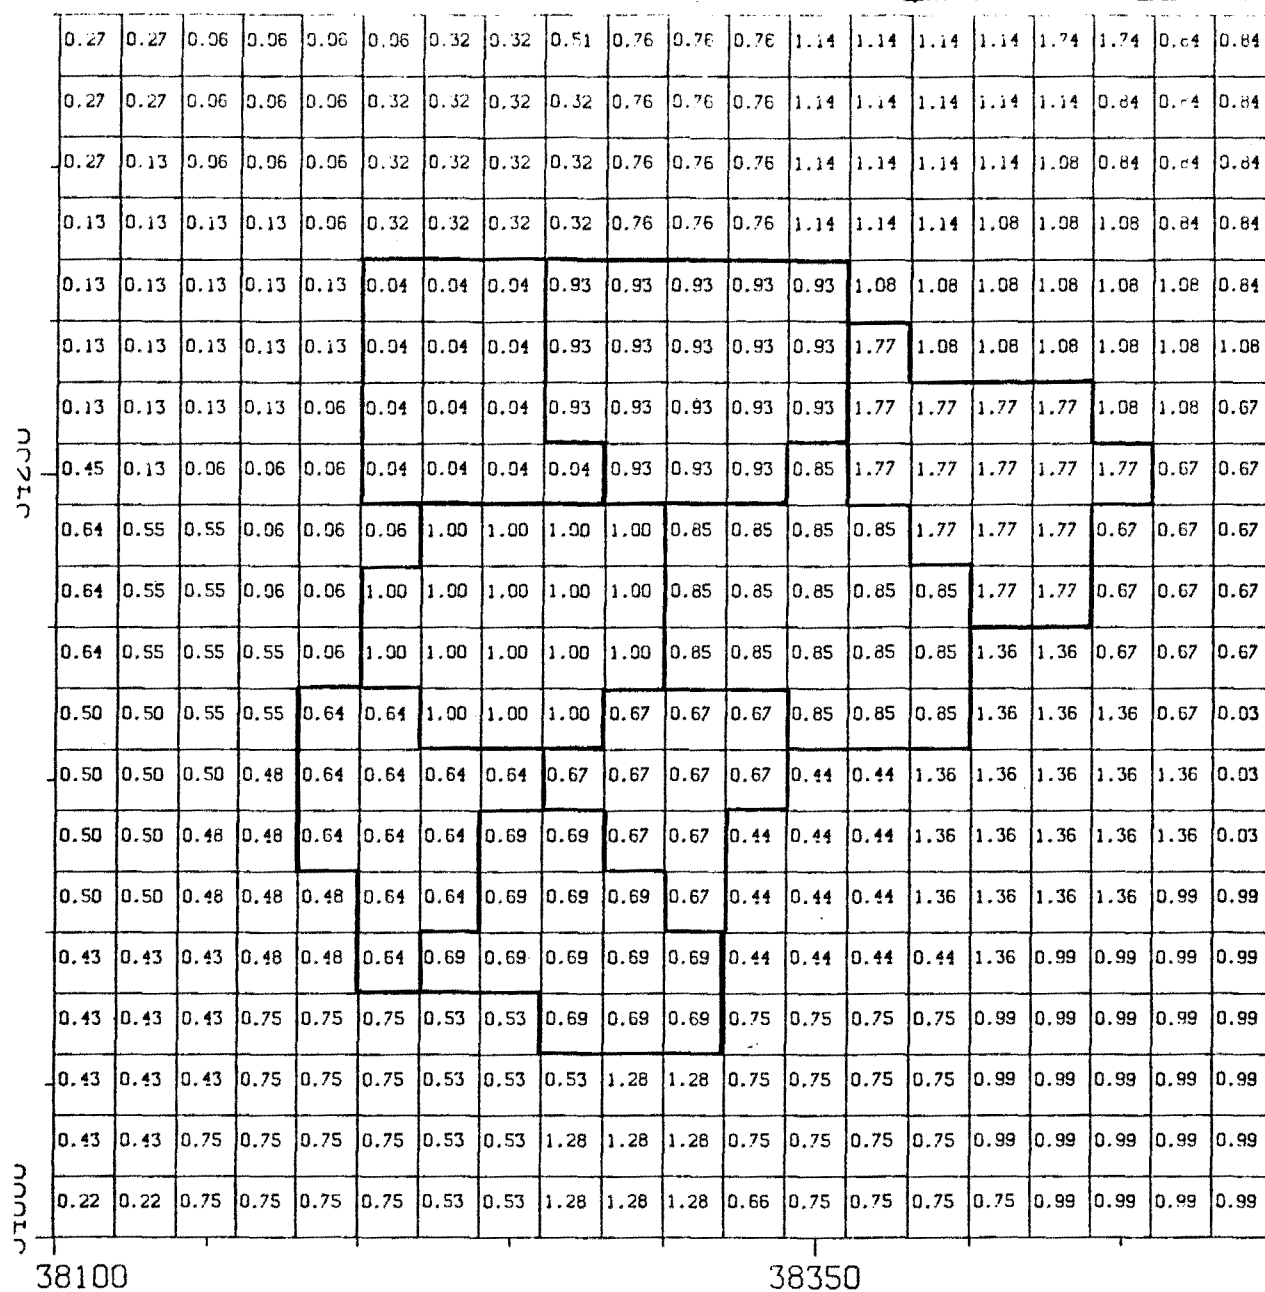

Fig. 2. Example of a standard block model with grade assignment by the polygonal methods.

Fig. 3. Approximate polygonal method. The grade of the closest drill hole, AM 148, is assigned to the block.

The choice of the maximum polygon size has always been quite subjective and based on the experience of the ore reserve practitioner. However, the maximum range of influence can be defined as the distance at which grade values are no longer correlated. This distance can be determined from a variogram study (see Section 3 for more information).

Characteristics of the Polygonal Method

The polygonal method of ore reserve estimation has been in use since the early 1900s (Popoff, 1966), and is still used by some companies, especially when manually preparing ore reserve estimates.

The polygonal method is unique among the estimators discussed in this section, because the polygons drawn around each drill hole define both the volume of ore and its grade. This aspect of the polygonal method means that it can be used both to estimate grades and to estimate the boundary of the mineral deposit. As an estimator of the boundary of a deposit, the polygon is unbiased and gives sharp boundaries rather than the smooth gradational boundaries an interpolation method such as inverse distance method would give.

As an estimator of grade values, the polygon does a poor job compared with the other estimators discussed in this section. In several case studies (Knudsen and Kim, 1978; Readdy et al., 1982; Baafi and Kim, 1981), the polygonal method has been found to give individual block estimates that have significantly greater error than inverse distance weighting or kriging. This is illustrated in Fig. 4. Of greater

danger than large errors in individual block estimates, however, is the fact that the estimates of blocks above cutoff will be biased. This is illustrated by Fig. 5, taken from Baafi, where the average error in estimated coal thickness increases as the thickness increases.

DISTANCE WEIGHTING INTERPOLATION METHODS

Several technological advances in ore reserve estimation and mine planning are directly attributable to the use of the computer. No longer was the ore reserve analyst limited to simplistic methods, such as the polygonal method, but could instead utilize various smoothing and interpolation methods that were simply too time-consuming without the computer. The development of the first computerized mine planning systems that were based on the standard block model also gave impetus for using interpolation methods to estimate the grade of ore in each block of the model. The development of computerized contouring programs also spurred the use of a variety of interpolation methods, because the contouring procedures require values on a regularly spaced grid.

Although a large variety of interpolation methods have been developed, this section will be limited to discussing several nonstatistical techniques in common use in the mining industry. The methods discussed are applicable both to estimating grades in a standard 3-D block model, or to estimating grades (or thickness, etc.) at each point in a 2-D grid such as is used to model coal seams.

Fig. 4. Histogram of estimation errors for various ore reserve methods (Baafi and Kim, 1982).

General Formulas

The object of interpolation is to predict the grade of a point or block by a weighted average of the nearby data points $Z(x_i)$. The general formula for distance weighting is

$$Z^*(v) = \sum_{i=1}^n \lambda_i Z(x_i)$$

and

$$\sum_{i=1}^n \lambda_i = 1$$

The weights, λ_i , are chosen as some function of the distance between the sample and the block. The most common form of weighting is to weight by the inverse of the distance raised to some power, r , as in:

$$\lambda_i = \frac{d_i^{-r}}{\sum_{i=1}^n d_i^{-r}}$$

Common choices of the power are 1, 1.5, 1.75, and 2. As the power gets larger, the faster the weights decay as d gets larger. The weight λ_i is not only a function of the power r , but also a function of the number of samples included in the interpolation. As more samples are included, the weight λ_i gets smaller; thus, the samples included in the interpolation are limited to those lying within a specified search radius.

Interpolation methods are susceptible to clustered data points, such as frequently occur in mining, where the clusters often occur in the high grade portions of the deposit (Ripley, 1981). This is shown in Fig. 6 where the cluster will dominate the other samples in estimating the value of point x .

One way to minimize this effect is to estimate the value of x using only a specified number of the nearest samples in each octant around x . This procedure is described by Sampson (1978) in the manual for *Surface II*.

Although the equation for distance weighting shows that the sample weighting is a function of the distance only, the weighting method can easily be altered to be a function of both distance and direction (Knudsen, 1975). This allows the effects of anisotropy in the mineralization to be included in the weighting.

An example of the calculations for a distance weighting interpolation method is shown in Fig. 7.

Validation of Interpolation Parameters

Specific values of the interpolation parameters used in a given interpolation should be chosen to give the optimal estimation. The only practical way to insure the best choice of the weighting exponent, the search radius, and the anisotropy factors is to validate the choices by using the comparison technique discussed earlier in this section. Using a specified set of parameter values, a comparison is made between the estimated grades of individual drill-hole composites and the true grades of the composites. Using this validation technique we can decide whether the exponent should be 1.75, 2.0, or some other value. The parameters giving the best estimation results are chosen for interpolation.

An example of this technique is shown in the following table. A comparison was made for six values of the weighting exponent.

Exponent	1.00	1.25	1.50	1.75	2.00	2.25	2.50	2.75
Error variance	1.89	1.87	1.88	1.89	1.91	1.94	1.97	2.01

Fig. 5. Errors in estimated grades for various cutoff grades (Baafi and Kim, 1982).

Fig. 6. Susceptibility of interpolation methods to clustered data points. The ten clustered points will dominate the rest for estimation at X (from Ripley, 1981).

Fig. 7. Example calculations for inverse distance squared weighting.

$$\lambda_1 = \frac{\frac{1}{32^2}}{\sum_{i=1}^6 \frac{1}{d_i^2}} = \frac{\frac{1}{32^2}}{\frac{1}{32^2} + \frac{1}{52^2} + \frac{1}{66^2} + \frac{1}{78^2} + \frac{1}{92^2} + \frac{1}{64^2}} = 0.464$$

likewise $\lambda_2 = 0.176, \lambda_3 = 0.109, \lambda_4 = 0.078, \lambda_5 = 0.056, \lambda_6 = 0.117$

$$Z^*(v) = \sum_{i=1}^6 \lambda_i Z(x_i)$$

$$= 0.464 \times 0.53 + 0.176 \times 0.69 + 0.109 \times 0.64 + 0.078 \times 0.48 + 0.056 \times 0.43 + 0.117 \times 0.75 \% \text{Cu} = 0.59 \% \text{Cu}$$

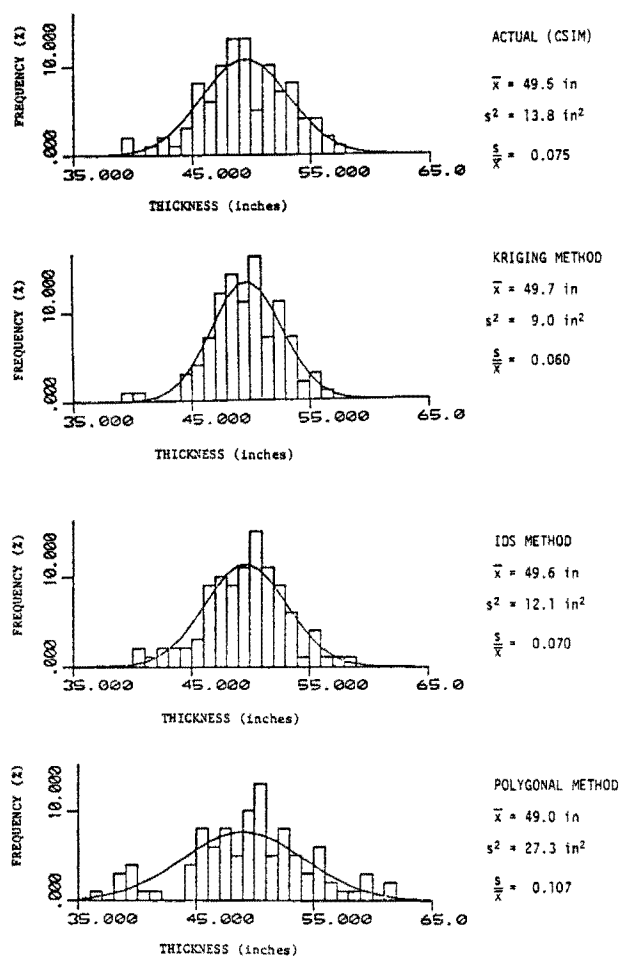

Fig. 8. Histograms of actual and estimated thickness.

The deposit was a large porphyry copper deposit and the samples used were 12-m (40-ft) composites. Notice that an exponent of 1.25 gave the lowest estimation variance. Further comparisons can be made to choose the maximum search radius and anisotropy factors. Kane, et al. (1982), have written a computer program called Program BESTP to automatically determine the best set of interpolation parameters.

Characteristics of Distance Weighting Method

Distance weighting interpolation methods have been widely used by the mining industry, especially for ore-body

modeling of open pit mines. Whereas the distance weighting interpolators largely replaced the traditional methods of estimation in the late 1960s, the distance weighting interpolators are now being rapidly replaced by the geostatistical technique of kriging.

Figs. 4 and 5 illustrate the reasons why the polygonal method fell out of favor to the distance weighting techniques, and why kriging is now becoming widely used. In theory, kriging should give estimates having the smallest estimation variance. This has been borne out in practice by many case studies. However, it should be noted in Fig. 4 that the estimation variance for the IDS (inverse distance squared weighting) and for kriging are not greatly different. With proper choice of the interpolation parameters the distance weighting techniques can give block estimates that are sometimes nearly as good as kriging. Fig. 5 shows that the IDS method has less conditional bias than does the polygonal method, but slightly greater bias than kriging.

Fig. 8 shows a comparison of the true distribution of block grades vs. the distribution of estimated block grades. Notice that both kriging and IDS result in distributions that are smoother (i.e., have less variance) than the true distribution of block grades. Also note that the polygonal method has a wider variance of block grades.

3.3 Statistical and Geostatistical Methods

JEAN-MICHEL RENDU AND GRAHAM MATHIESON

INTRODUCTION

The economic value of a mineral deposit is first a function of its ore reserves. During the exploration and feasibility phases of a mining project, the need for timely and reliable ore reserve estimates is of critical importance particularly as a basis for mine planning in the early production years. This is a first step in assessing the economic merit of a deposit and must be done to permit monitoring of the appropriateness of continued capital investment in the project.

Underestimation of reserves may result in rejection of a viable project, significant opportunity losses, and possible embarrassment if the deposit is later successfully mined by a competing company. Overestimation may result in the inappropriate development of a subeconomic deposit, disappointing results, and significant financial losses. Poor evaluation may also lead to an undesirable mine development sequence, improper mill design, and inappropriate mining equipment selection.

Once in production, reserves and local block grades are reevaluated periodically for medium- and long-range planning, perhaps annually, down to weekly or even daily for short-term planning and grade control. Poor reserve estimation will result in waste blocks being predicted as ore, while ore blocks will be treated as waste, with direct impact on the grade of anticipated mill feed and cash flow. The precision that can be attained in each evaluation will vary significantly with the information available, including sampling and mapping data as well as the current understanding of the deposit geology. Similarly the method to be used for reserve evaluation must be adapted to take into account the quantity and quality of information to be processed, as well as the purpose for which the reserve estimate is to be made.

Whatever the amount of effort put into the calculation of the reserves, some degree of uncertainty will remain concerning the true characteristics of the deposit. This is a direct consequence of the need to estimate the properties of thousands of tons of material from samples whose total weight may only be a few kilograms. The overall precision with which the reserves are estimated is a function of numerous factors, including the type of mineralization, the geologic complexity of the deposit, the quality and quantity of sample information available, as well as the methodology used to process this information.

Considering the complexity of the parameters that must be taken into account and the interdisciplinary nature of the studies required, reserve estimation must be a team effort, involving geologists, mining engineers, mineral process engineers, statisticians, and, usually, computer specialists. Furthermore, in all instances where the quality of the reserve estimates is likely to have a significant influence on the financial and economic health of a mining company, high level executive attention should be given to the study to ensure not only that the correct answer is obtained, but that its meaning and its basis is also fully understood.

The main purpose of this chapter is to present the principal statistical and geostatistical techniques of ore reserve estimation as they apply to surface mining operations. To fully appreciate both the power and the limitations of these

techniques, the preceding remarks should be kept in mind throughout. They were very aptly summarized by the authors of an excellent guide to the understanding of ore reserve estimation published by The Australasian Institute of Mining and Metallurgy (King, et al., 1982):

"Ore reserve estimation is not a matter of mere calculation but a procedure which involves, explicitly or implicitly, judgment and assumption about geological, operational and investigational factors. The calculations therefore form only part, and not necessarily the most important part, of the overall procedures.

An ore reserve statement should, where appropriate, be not merely an estimate of what is in the ground but a prediction, involving a further stage of judgment and assumption, of what will be fed to the mill or recovered.

For practical and statistical reasons related to the limitations of sampling and the kind and character of the ore, accuracy of prediction, especially of grade, will rarely exceed and will commonly not reach two significant figures."

Statistical methods of reserve evaluation do not take into account the physical position of the samples with respect to each other. They are extremely useful in the early analysis of a deposit and can be used to verify and interpret the sample values available, as well as to obtain preliminary reserve estimates. Geostatistical methods, on the other hand, are based on the common observation in mineral deposits that samples taken close to each other are more likely to have similar values than if they are located far apart. For this reason they are particularly well adapted to detailed reserve evaluations, when relatively dense sample information is available.

Statistical and geostatistical methods take into account the variability in an ore body's mineralization, and can be used to quantify the uncertainty associated with the reserve estimates. As with any other reserve estimation procedure, considerable judgment is needed in the use of geostatistics but the methods are easily adapted to take into account the specific properties of each deposit, the nature of the sample information available, the degree of continuity present in the mineralization, as well as the geologic controls that may influence the ore distribution. For this reason, geostatistics is increasingly becoming accepted as an adaptable method, likely to give improved estimates in most situations (Clark, 1979; David, 1977; Journel, et al., 1978; Rendu, 1981; Royle, 1980).

STATISTICAL METHODS

Introduction

Traditional statistical methods are based on the assumption that all sample values are equally representative of the properties of the deposit under study. The physical position of the samples with respect to each other is not taken into account. For this reason, application of these methods to reserve evaluation is usually limited to the early stages of ore body analysis, when a global estimate is sufficient, or to the study of highly variable mineralizations in which the similarity between sample values is negligible, even at short distances. Statistical methods are also extremely useful to test the reasonableness of estimates obtained using more sophisticated approaches, such as kriging. Many of the visual

and mathematical tools described here can also assist in the analysis, verification, and interpretation of sample data and in this respect they may be found useful throughout the life of a mining project.

Perhaps the easiest and fastest method of estimating the average grade of a deposit, or part of a deposit, consists of calculating the average value of the samples in the area of interest, ignoring their relative position. As an example, if a coal seam is intersected by ten drill holes and the seam thickness is measured in each hole, the average thickness of the seam can be estimated by the mean value of the ten drill-hole intercepts. If the drill holes are approximately uniformly distributed, this estimate is likely to be perfectly acceptable. Simple statistical formulae can then be used that give reasonable preliminary estimates of the coal tonnage in the deposit and the precision with which it is known.

If on the other hand, we consider an uranium vein which has also been intersected by ten drill holes, and want to estimate the average grade times thickness (uranium accumulation measured in meter \times %U308), the average value of the ten drill holes is likely to give a very poor estimate of the vein properties. Indeed, the uranium accumulation may vary from a minimum of say 0.01 %U308 over 0.5 m (1.6 ft) [0.005 m (0.02 ft) \times %U308] to a maximum of say 1.00% U308 over 1.5 m [1.5 m (5 ft) \times %U308], and the mean value of the ten drill holes will be extremely sensitive to the presence of extreme values, especially extremely high values. In such instances where a very high level of variability is observed, more complex statistical methods may be required.

Visual Methods of Statistical Analysis

The first step in a statistical analysis of a mineral deposit involves plotting the *histogram* of the sample values. To calculate a histogram, the values are first sorted in increasing order. They are then grouped into class intervals and the number of samples falling within each class is calculated. Examples of histograms are given in Fig. 1 for a coal seam. The heat contents of the corresponding samples are listed in Table 1. These values have been grouped in increments of 0.23 MJ/kg (100 Btu per lb) as shown in Table 2 and the histogram plot shows, for example, that five samples have heat contents between 23 (9900) and 23.3 MJ/kg (10,000 Btu per lb).

Histograms can be extremely instructive. They show the range of values that can be expected, and they can be used to detect extreme, possibly erroneous values. The value that is occurring most often can be visually determined. It is known as the histogram *mode*. The midpoint value below which 50% of the samples are likely to be located is the histogram *median*.

In the foregoing example, the heat content varies from 21.2 to 23.8 MJ/kg (9000 to 10,100 Btu per lb), the most likely heat content is between 22.7 and 22.9 MJ/kg (9600 and 9700 Btu per lb) and the median is 22.88 MJ/kg (9697 Btu per lb). Histograms can also help to detect mixtures of geologic environments (Fig. 2).

From the histogram, the *frequency distribution* can be calculated where the number of samples falling in a given class interval is replaced by a proportion given as a percentage of the total number of samples. For example, Table 2 shows that 18.37% of the samples have a value between 22.7 and 22.9 MJ/kg (9600 and 9700 Btu per lb). If the samples shown in this table are representative of the actual coal seam, this distribution also indicates that 18.37% of the entire deposit has a value between 22.7 and 22.9 MJ/kg (9600 and

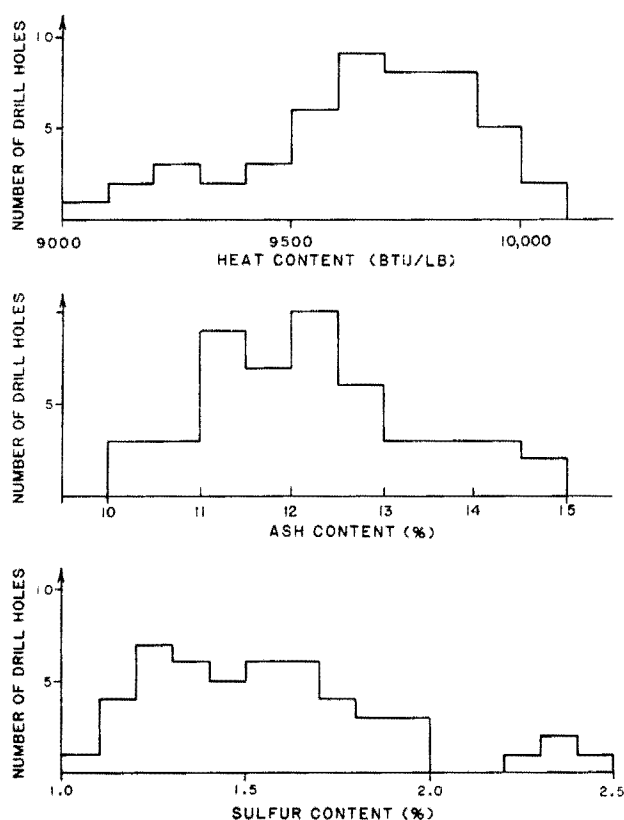

Fig. 1. Examples of histograms from a coal seam.

9700 Btu per lb). Extreme care must, however, be applied when using sample statistics to determine the economic properties of deposits that can only be mined using panels or blocks of size significantly larger than the samples. The influence of block size and selectivity on the grade-tonnage relationship is the subject of extensive discussions later in this section. Sample statistics will give reasonable estimates when applied to deposits with relatively low variability such as coal or industrial minerals. Only an order of magnitude estimate will be obtained if highly variable values are studied, such as gold or uranium grades.

Another tool that is useful in the statistical study of sample values is the *cumulative frequency distribution*, that indicates the proportion of the samples with value less than a given upper limit. Looking again at Table 2, one sees that 34.69% of the samples have a heat content of less than 22.7 MJ/kg (9600 Btu per lb). This also means that 65.31% of the sample values exceed 22.7 MJ/kg (9600 Btu per lb). Again, if the samples are representative of the deposit, one

9000	10100	49	100%	100%

* To convert to MJ/kg multiply by 2.326^{-3} .

may be able to conclude that 65.31% of the entire deposit will exceed 22.7 MJ/kg (9600 Btu per lb).

Cumulative frequency distributions are usually plotted using a probability scale along the horizontal axis. The probability scale is such that if the sample values are approximately normally distributed, the cumulative frequency distribution will be well represented by a straight line. The cumulative frequency distribution of the sample values listed in Table 2 is plotted in Fig. 3.

Another graphical representation of the distribution of sample values which is extremely helpful in understanding the properties of a deposit is the *scatter diagram*. A scatter diagram can only be plotted if at least two values are available for each sample. Scatter diagrams for a coal deposit are shown in Fig. 4. These diagrams show a positive but weak correlation between ash content and sulfur content, no correlation between seam thickness and heat content, a strong negative correlation between ash content and heat content, and a weak negative correlation between sulfur content and heat content. These plots can be used to detect anomalous values, as well as mixture of geologic populations (Fig. 5).

The use of such graphical methods for the preliminary analysis of sample values is usually extremely instructive. One should, however, remember that such methods can give meaningless results unless the geology of the deposit is first

taken into consideration to classify the sample values. The spatial distribution of the samples and drill holes must be kept in mind when interpreting the results. For example, frequency distributions may be meaningless if the drill holes analyzed are located on a 50-m (164-ft) grid in the high grade part of the deposit and a 200-m (656-ft) grid in the lower grade parts of the deposit. Finally, all statistical analyses require that the values analyzed correspond to samples, composites or blocks of constant size. Using geostatistical terminology, it will be said that the values must correspond to *supports* of constant size.

The concept of support size is extremely important in all statistical studies of geological data. This is clearly seen in Fig. 6 that shows the grade of samples of variable size on the right-hand side, while the corresponding average grade of composites of 3-m (10-ft) length is plotted on the left-hand side. The sample size varies from 3 cm (0.1 ft) to 9 m (29.5 ft). The highest sample assay is 2.0% over 3 cm (0.1 ft), while the composites do not exceed 1.0%.

A numerical example of the influence of support size is shown in Fig. 7. Channel samples of 1-m (3.3 ft) length have been taken along a drift in a high-grade copper deposit. The values of the 1-m samples vary from 1% to 15%, while 8-m (30.6-ft) composites remain between 5.25% and 8.25%. Also shown in this figure is the effect of the support size on the frequency distribution. Typically, when the support size increases, the values get closer to each other and, therefore, closer to the mean of the ore body. Similarly, if longer or larger samples are used to analyze a deposit, the variability of the corresponding values is likely to be reduced, unless an increase in assaying errors counters the effect of the decreased geologic variability.

Fig. 8 illustrates the hypothetical distribution of all 3-m (10-ft) samples and 15-m (49-ft) composites in a porphyry copper deposit. If a 0.5% Cu cutoff grade is applied to the 3-m (10-ft) samples, 55% of the deposit is above cutoff, averaging 1.5% Cu. On the other hand, if the same cutoff grade is applied to 15-m (49-ft) composites, 65% of the deposit is above cutoff, averaging 1% Cu. Clearly, mining will occur at a scale greater than 3-m (10-ft) samples or even 15-m (49-ft) composites. Blocks of size $15 \times 15 \times 15$ m ($49 \times 49 \times 49$ ft) might be considered as selectively minable, whose distribution will show even less variability than the one exhibited by the 15-m (49-ft) composites and will typi-

Fig. 4. Examples of scatter diagrams.

Fig. 5. Scatter diagrams indicating errors and mixture of geologic environments.

cally result in higher tonnage and lower grade estimation. Geostatistical methods exist that can be used to estimate the distribution of block grades from the sample distribution. These methods will be discussed later.

Normal Distributions

The methods described here apply to normally distributed sample values, i.e., values whose frequency distribution

is symmetrical around the mean and can be plotted as a straight line on probability paper (Fig. 3). These methods are also commonly used when the sample values are only approximately symmetrical, but not necessarily normally distributed (Fig. 1). They can also be applied to large number of samples, independent of their distribution, under conditions specified later. Examples of deposits to which these methods can be applied include iron, coal, potash, phosphate, and industrial minerals as well as some high grade base metal ore bodies. Seam or vein thicknesses can also often be treated in the same fashion.

If n samples have been taken from a mineral deposit, with values x_i , $i = 1, 2, \dots, n$, an estimate of the average value of the deposit is the sample *mean* \bar{x} :

$$\bar{x} = \frac{1}{n} (x_1 + x_2 + \dots + x_n)$$

For example, if five drill holes intersect a coal seam indicating coal thicknesses of 5, 2, 7, 4, and 3 m, (16, 6.6, 23, 13, and 10 ft), respectively, the average thickness of the deposit can be estimated at 4.20 m (13.8 ft). This number is, however, only an estimate of the true average coal thickness which could be thicker [say 5 m (16 ft)] or narrower [say 3 m (10 ft)]. The degree of certainty with which the deposit characteristics are known is a function of the number of samples available, the variability in the sample values, and of whether the sample values are truly representative of the deposit. If μ is the unknown average thickness of the deposit, \bar{x} is an estimate of μ . The difference between \bar{x} and μ represents the

error made in estimating the deposit parameter in question. This difference is unknown, but statistical methods can be used to quantify its likely magnitude. The expected value ($E[\]$) of the squared difference between \bar{x} and μ is known as the *error variance* σ_E^2 :

$$\sigma_E^2 = E[(\bar{x} - \mu)^2]$$

and its square root σ_E is the (standard) error of estimation of μ . The magnitude of σ_E gives an indication of the precision with which the mean is estimated. In many circumstances it is reasonable to state that there are two chances in three (68% probability) that the true value μ is greater than $\bar{x} - \sigma_E$ and less than $\bar{x} + \sigma_E$. There are also approximately 19 chances in 20 (or 95% probability) that the true value of the deposit exceeds $\bar{x} - 2\sigma_E$ and is less than $\bar{x} + 2\sigma_E$. The error variance is calculated from the estimated sample variance s^2 as follows:

$$s^2 = \frac{1}{n-1} [(x_1 - \bar{x})^2 + \dots + (x_n - \bar{x})^2]$$

$$= \frac{1}{n-1} \left(\sum_{i=1}^n x_i^2 - n\bar{x}^2 \right)$$

$$\sigma_E^2 = s^2/n$$

Using the coal seam example given previously, we calculate $n = 5$, $s^2 = 3.70$, and $\sigma_E^2 = 0.74$ or $\sigma_E = 0.86$ m. Therefore if μ is the unknown average thickness of the deposit,

$$\text{Prob } (3.34 \text{ m} < \mu < 5.06 \text{ m}) = 68\%$$

$$\text{Prob } (2.48 \text{ m} < \mu < 5.92 \text{ m}) = 95\%$$

If the sample values reasonably well approximate a normal distribution, the confidence intervals can be calculated with increased precision, using the Student's t statistics, a method described in detail in most texts on statistics or geostatistics (David, 1977; Rendu, 1981).

The foregoing formulae can generally be applied to most deposits, independent of whether or not the sample values are normally distributed, provided the number of samples is large enough, such that the error of estimation σ_E does not exceed 20% of the mean.

Lognormal Distributions

In many more deposits the sample distribution is not symmetrical, but is characterized by a longer tail towards the high values (Fig. 9): this is known as a positively skewed distribution. This type of distribution is extremely common among lower grade deposits, characterized by a high variability in sample values. It is commonly observed not only in gold and precious metal deposits, but also in uranium, tin, molybdenum, copper, and zinc deposits, as well as in the sulfur content of coal deposits and in the thickness of extremely variable veins. If sample values have a very skewed distribution, the simple statistical methods discussed earlier in the context of the normal theory may give meaningless results.

In many instances, as illustrated in Fig. 10, the frequency distribution of the sample values will plot as a straight line on logarithmic probability paper. The distribution is then said to be lognormal and the logarithms of the sample values are normally distributed. Logarithmic probability paper is characterized by a probability scale on the horizontal axis and a logarithmic scale on the vertical axis. The data plotted in Fig. 10 are listed in Fig. 9. Also shown in Fig. 10 are graphical methods of analysis of lognormal distributions that are discussed by Krige (1978) and Rendu (1981). The lognormal distribution of sample values was first recognized by Dr. Sichel in the South African gold fields (Sichel, 1952).

In some instances, the lognormal assumption is not exactly satisfied and the cumulative frequency distribution shows a downward curvature when plotted on lognormal probability paper (Fig. 11). D. G. Krige showed (1960) that a lognormal distribution can often be obtained if a constant is added to the sample values. The distribution is then said to be three-parameter lognormal. The three parameters are the mean, the logarithmic variance, and the additive constant. The additive constant is best determined graphically by trial and error, using a plot of the cumulative frequency distribution.

A simple example will be used to indicate some of the properties of the lognormal approach. Consider a block of ore from a gold deposit in which seven blastholes are located, having assays of 10, 11, 12, 15, 18, 20, and 200 milliounces* per ton (moz/ton) (Block 3 in Fig. 12). If the normal statistical methods discussed earlier are used to analyze this block, its average grade is estimated at 40.9 moz/ton, with 90% probability that the true average grade of the block is at least 0 moz/ton (the calculated value is -10.7 moz/ton) but not more than 92.5 moz/ton. The confidence limits were calculated using the Student's t statistics, and the lower limit is obviously meaningless. If, on the other hand, lognormal statistical methods are used, the block average grade is estimated at 31.5 moz/ton, with 90% probability that the true average grade is at least 16.7 moz/ton but not more than 163.6 moz/ton. These numbers appear more reasonable and reflect one of the properties of the lognormal theory; namely that it is less sensitive to extreme values. The downside risk, as represented by the lower confidence limit, is also better bounded. The two other examples given in Fig. 12 (Blocks 1 and 2) show only a small difference in results when applying

* 1 milliounce = 0.001 oz.

normal and lognormal theory to data with relatively low variability. Unfortunately, this example should not be taken to imply that a lognormal approach is always preferable, as there are cases where it will also give meaningless results.

Consider n sample values x_i , $i = 1, 2, \dots, n$ taken from a lognormal distribution with additive constant β . If we define $y_i = \ln(x_i + \beta)$, the logarithmic mean and logarithmic variance are estimated as follows:

$$\bar{y} = \frac{1}{n} (y_1 + y_2 + \dots + y_n)$$

$$V = \frac{1}{n} [(y_1 - \bar{y})^2 + \dots + (y_n - \bar{y})^2]$$

The median of a lognormal distribution is estimated by $m = \exp(\bar{y}) - \beta$. In first approximation if n is larger than 20 and V is less than 2.0, the mean value of the deposit can be estimated by T calculated as follows:

$$T = \exp(\bar{y} + V/2) - \beta$$

Upper and lower confidence limits for this mean value can be estimated using the following formula:

$$T_p = (T + \beta)\psi_p(V; n) - \beta$$

with:

$$\psi_p(V; n) = \exp\left(\frac{\sigma^2}{2} + t_p\sigma\right)$$

$$\sigma^2 = \frac{V}{n} \left(1 + \frac{V}{2}\right)$$

and where t_p is the Student's t statistic.

The values $t_p = -1$ and $t_p = +1$ can be used to calculate the lower and upper 68% confidence limits. Values $t_p = -2$ and $t_p = +2$ can be used to calculate the lower and upper 95% confidence limits. For example, consider a molybdenum deposit from which 30 samples have been taken with a three-parameter lognormal distribution, the additive constant having value $\beta = 0.02$ Mo%. The logarithmic mean and logarithmic variance are first calculated, say $\bar{y} = -2.30$ and V

$= 1.2$. The average grade of the deposit is estimated at $T = \exp(-2.30 + 1.2/2) - 0.02 = 0.163$ Mo%. Furthermore, $\sigma^2 = (1.2/30)(1 + 1.2/2) = 0.064$; hence there is approximately 95% probability that the average grade of the deposit is at least $(0.163 + 0.02) \times \exp(0.064/2 - 2\sqrt{0.064}) - 0.02 = 0.094$ Mo% but not more than $(0.163 + 0.02) \times \exp(0.064/2 + 2\sqrt{0.064}) - 0.02 = 0.293$ Mo%.

The foregoing formulae are only approximations and are not necessarily acceptable when the number of samples becomes small. For these conditions, Dr. Sichel developed exact statistics which require use of tables, as can be found in Sichel (1966), Rendu (1981), Krige (1978), David (1977) or Wainstein (1975). The average value μ is then estimated by the Sichel's T estimator defined as follows:

$$T = \exp(\bar{y}) \gamma_n(V) - \beta$$

where $\gamma_n(V)$ is obtained from tables. Confidence limits for the value μ are calculated using the formula:

$$T_p = (T + \beta) \psi_p(V; n) - \beta$$

where $\psi_p(V; n)$ is also obtained from tables. The mathematical formulae that can be used to calculate $\gamma_n(V)$ and $\psi_p(V; n)$ are discussed by Sichel (1966) and Wainstein (1975).

Lognormal theory was first successfully used in the 1950s in the evaluation of South African gold mines, where it was commonly necessary to achieve accurate estimation of new deposits from a small number of drill-hole intercepts. It has been used extensively since then in many types of deposits,

including disseminated and vein gold, molybdenum, tin, sulfur in coal deposits, bismuth in zinc deposits, lead, copper, zinc, and uranium.

In many instances, the distribution of the sample values well approximates the two- or three-parameter lognormal model. In other instances, significant departure from these models may be observed. Such departures may be indicative of a number of factors, including the superposition of a number of mineralizing events, or simply that the grade distribution is indeed not lognormal. In all instances, simple explanations should first be sought for complex value distributions. An irregular sampling density will often result in an excessive representation of the high-grade portions of the deposit. A mixture of geologic environments may also produce apparently abnormal distributions. The presence of clay zones in the middle of a disseminated gold deposit may result in an excess of low-grade values. Secondary enrichment may, on the other hand, result in an excess of high-grade values. Changes in the sampling density can be taken into account by using declustering techniques that consist in weighting the sample values in inverse proportion to the drill-hole density. If mixed geologic zones are suspected, additional geologic analysis and partitioning of the deposit may be required before meaningful statistical results can be obtained.

Once again it should be emphasized that conventional statistical methods, even though limited in their application, still have an important role to play in checking and sorting out data, as well as in the controlled estimation of reserves under specific conditions.

Fig. 12. Statistics: Lognormal distribution.

A number of frequency distributions that well approximate either two- or three-parameter lognormality are shown in Fig. 13.

Correlation and Regression Analysis

Some additional statistical definitions must be introduced here whose utility in the geostatistical analysis of mineral deposits will be seen later. Consider two sample or drill-hole characteristics x and y . For example, x may be copper grade and y the corresponding zinc grade of a sample. Alternatively x may be the thickness of a vein deposit and y the corresponding average grade. If n samples have been taken, with values x_i and y_i , $i = 1, \dots, n$, a scatter diagram can be plotted (Fig. 14). The relationship between x and y can be quantified by the covariance σ_{xy} calculated as follows:

$$\sigma_{xy} = \frac{1}{n-1} [(x_1 - \bar{x})(y_1 - \bar{y}) + \dots + (x_n - \bar{x})(y_n - \bar{y})]$$

where \bar{x} is the mean of x_i and \bar{y} is the mean of y_i . A positive covariance indicates that y tends to increase with x . The value of σ_{xy} is a function of the variability of x and y . For this reason a scaled statistic, the *correlation coefficient*, is preferred. If σ_x^2 is the variance of x and σ_y^2 is the variance of y , the coefficient of correlation of x and y is ρ_{xy} defined as follows:

$$\rho_{xy} = \sigma_{xy} / \sigma_x \sigma_y$$

This coefficient can take values between -1 and $+1$. Examples are shown in Fig. 14.

Fig. 13. Examples of cumulative frequency distributions.

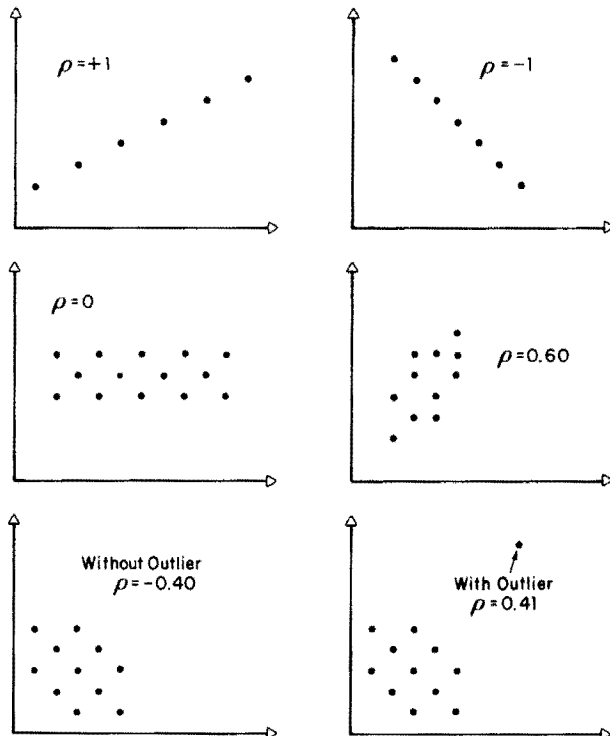

Fig. 14. Examples of correlation coefficients.

One must be careful when interpreting coefficients of correlation. Values close to 1 or -1 usually indicate a strong correlation, while values close to zero indicate a poor or no correlation. However, outliers, extreme values, or incorrect values may result in a meaningless correlation coefficient. For this reason it is recommended that scatter diagrams be plotted before calculating the correlation coefficient. This is illustrated in the lower part of Fig. 14.

In some instances it is desirable to estimate the value of a variable y from the value of x . For example, in a massive sulfide deposit, x might represent the copper grade and y the specific gravity. In simple cases, linear regression can be used for this purpose. The expected value of y given x is \hat{y} calculated as follows:

$$\begin{aligned}\hat{y} &= ax + b \\ a &= \sigma_{xy} / \sigma_x^2 = \rho_{xy} \sigma_y / \sigma_x \\ b &= \bar{y} - a\bar{x}\end{aligned}$$

The error made when estimating y by \hat{y} is given by the following formula:

$$\sigma_E^2 = E[(y - \hat{y})^2] = \sigma_y^2(1 - \rho_{xy}^2)$$

If the sample values x and y are lognormally distributed, the covariance and variances should be calculated using the logarithm of the sample values. The following regression equation must then be used (David, 1977):

$$\hat{y} = \exp \left[a \ln(x) + b + \frac{1}{2} \sigma_y^2 (1 - \rho_{xy}^2) \right]$$

When using regression analysis, it is important to realize that the regression line is not the same depending on which variable is treated as the y (*dependent*) variable, and which is treated as the x (*independent*) variable.

THE FOUNDATIONS OF GEOSTATISTICS

The Geostatistical Approach

The statistical methods described earlier permit the estimation of the average value of a deposit parameter and the calculation of confidence limits for this value. They are based on the very important assumption that sample values are independent of one another and are equally representative. It has been demonstrated that these methods yield unreliable results when the drill-hole spacing is highly variable but they also suffer from at least two other major deficiencies. Under many circumstances, they lead to an incorrect estimate of the certainty with which the deposit is known. They can also be extremely unreliable for the essential task of estimating the value of a subset of an ore body such as a block, panel, mine section or bench.

As soon as a reasonable number of samples has been obtained from the deposit, the assumption of the independence of these samples becomes invalid and represents in fact an ignoring of an important portion of the knowledge gained during the sampling program, i.e., the relationships between the sample values and their relative positions. Whatever method is used for the valuation of a block of ore, the following assumptions are always made:

- 1) The values of samples located near or inside the block being estimated are related to the value of the block and, most importantly,
- 2) The values of the samples located closest to the block are most closely related to the value of the block.

These assumptions will hold true only if the following condition is also satisfied, as it is in virtually every known type of mineral deposit:

- 3) There exists a relationship between sample values which is a function of their distance apart.

The geostatistical method of ore reserve estimation is distinguished from other methods available by its inclusion of this factor. At the outset, it involves estimating the spatial relationship that exists between the known sample values and from that estimation deriving a model of this relationship for the ore body or some zone within it. This model is then used to calculate the relationships between the known sample values and the unknown block values and thus to produce the best possible estimate of this block value.

The Semivariogram

Definition: Once a geologic understanding of the deposit has been obtained and preliminary nonspatial statistics have been completed, more complex statistical methods, that take into account the relative position of the sample values, must be used.

It is obvious that samples located a few meters (feet) apart are likely to indicate similar properties of the mineralization, and that this similarity would be expected to de-

crease when the distance between holes increases. In some deposits, it may be possible to define a distance of influence beyond which the similarity between sample values becomes negligible. However, this distance may vary significantly between deposits, between different parts of the same deposit, or even between different directions at the same point in the deposit. This degree of similarity or dissimilarity between values can be quantified and can be of great assistance in understanding the properties of the deposit and optimizing its evaluation.

The simplest method of comparing two sample values is to calculate the difference between them: the smaller the difference the more similar the values. Generally, when the distance between samples increases, the difference between values increases. Rather than working with differences between sample values that can be positive or negative, the geostatistician uses the average squared difference, also known as the *variogram*. The value of the *semivariogram* $\gamma(h)$ for a distance h between samples is equal to *one-half* the average squared difference between sample values. The one-half factor is used such that the values of the semivariogram are equivalent to variances.

The general formula for calculation of the semivariogram is:

$$\gamma(h) = \frac{1}{2n} \sum_{i=1}^n (x_i - x'_i)^2$$

where n is the number of pairs of samples a distance h apart, x_i is the value of first sample in i th pair, and x'_i is the value of second sample in i th pair.

This definition is best explained through an example:

A bedded deposit has been intersected by ten drill holes located on a straight line as shown in Fig. 15. Most drill holes are 1000 ft (304 m) apart and the thickness of the deposit has been measured at each point. The semivariogram value for a distance of 1000 ft (304 m) between holes is calculated as follows:

$$\begin{aligned} \gamma(1000) &= \frac{1}{2} \cdot \frac{(5-5)^2 + (5-7)^2 + (12-11)^2 + (11-8)^2 + (8-7)^2 + (7-2)^2 + (3-3)^2}{7} \\ &= 2.86 \end{aligned}$$

For a distance of 2000 ft (608 m) between holes the following results are obtained:

$$\begin{aligned} \gamma(2000) &= \frac{1}{2} \cdot \frac{(5-7)^2 + (7-12)^2 + (12-8)^2 + (11-7)^2 + (8-2)^2 + (2-3)^2}{6} \\ &= 8.17 \end{aligned}$$

A similar calculation for 3000 ft (912 m) gives a result of 15.67. These results are plotted in Fig. 15.

Calculations: One Dimensional—The example given in the previous section illustrates how the semivariogram can be calculated in a one-dimensional environment. If channel samples were taken at regular intervals along parallel drifts, the semivariogram will be calculated within each drift as indicated in the foregoing example and then averaged between drifts. If a number of vertical drill holes were drilled and samples of equal length and diameter were taken and assayed using identical methods, an average downhole semivariogram can be calculated. If the drill holes are located on a regular grid, between-hole semivariograms can be calculated in the same fashion.

If the samples are not of equal length, they should be first grouped or divided to form composites of equal length. As indicated earlier, statistics calculated on values corresponding to *supports* of variable size are usually meaningless.

Fig. 15. Calculation of semivariogram.

If a number of drill-hole sizes, sampling methods, or assaying methods were used, each data set should be statistically analyzed separately. If the statistics indicate no significant difference, it may be possible to combine different types of data in the semivariogram calculation.

In many instances, it may be necessary to use sample values that are not strictly comparable. This is commonly the case when a deposit has been analyzed over a number of periods by different operating companies using different types of equipment. Minor differences such as in drill-hole diameters can often be ignored. But chip samples taken along a drift should not be combined with core samples taken ahead of drifting.

Two-Dimensional—When a vein or bedded deposit is analyzed, the values of interest can often be treated two-dimensionally. The information supplied by each drill-hole intercept is reduced to an ore thickness and an average grade between hanging wall and footwall. The grade values can be analyzed directly or alternatively the product of grade times thickness (the accumulation) can be calculated. The thickness analyzed may be either the true thickness or the thickness measured normal to a reference plane, this being either a horizontal or vertical plane or a dipping plane parallel to the deposit. If, in the reference plane case, the drill holes are approximately located on a regular grid the semivariogram can be calculated using a grid search as shown in Fig. 16a.

The direction and distance between samples whose value is to be compared, is specified by a number of blocks n_i in the east direction and n_j in the north direction. Fig. 16a shows the pairs of samples to be considered in the following directions: east-west, north-south, northeast-southwest, and north 33.7° east ($n_i/n_j = 2/3$).

This grid search method is also applicable when a very large number of sample values is available for analysis, as may be obtained by blasthole sampling or underground channel sampling for grade control. The sample values can then be averaged within blocks of equal size and the semivariogram is calculated between the block averages. Compared with other methods of semivariogram calculations, the grid search method is remarkably inexpensive.

The method commonly used to calculate the semivariogram in a two-dimensional environment is illustrated in Fig. 16b and uses an angular search. The value of the semivariogram is to be estimated in a direction α for a distance h between samples. If the reference plane is horizontal, α will represent the azimuth. Two samples with value x_1 and x_2 will be considered in this estimation, provided (1) the direction defined by these two samples is greater than $\alpha - d\alpha$ and less than $\alpha + d\alpha$, and (2) the distance between samples is greater than $h - dh$ and less than $h + dh$. $d\alpha$ and dh are the tolerance angle and distance that should be kept small whenever possible. The result obtained is an estimate

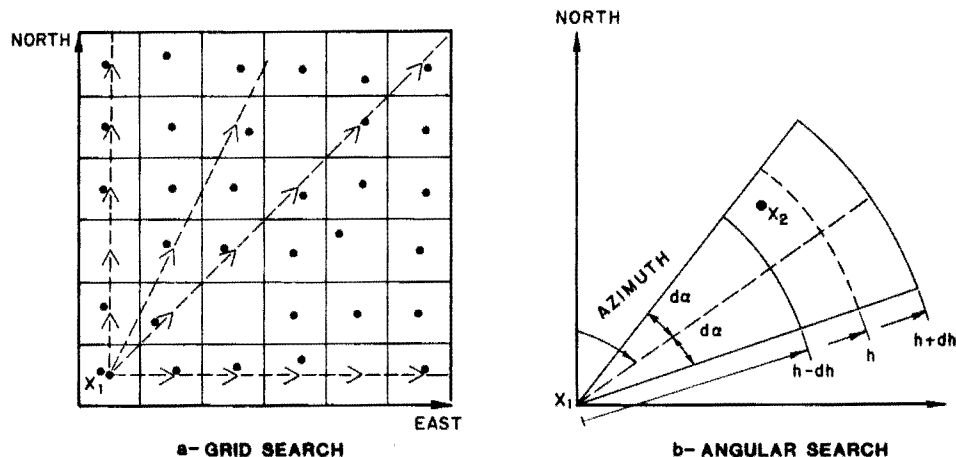

Fig. 16. Two-dimensional search.

Fig. 17. Drill hole location map and drill hole values, test case ore body.

of the average value of the semivariogram when the distance between samples varies from $h - dh$ to $h + dh$ and the direction varies from $\alpha - d\alpha$ to $\alpha + d\alpha$. The average distance between the samples used to estimate the semivariogram should always be calculated, as it may be significantly different from the nominal distance h if the sample pattern is highly irregular. The average direction corresponding to the pairs of samples retained, can also be used in graphical representations.

Consider the 25 sample values given in Fig. 17. Their cumulative frequency distribution is shown in Fig. 18. It differs only slightly from a normal distribution. The semivariogram has been calculated in the following directions: north-south, northeast-southwest, east-west, northwest-

southeast. An angular tolerance of 22.5° was used. The distances considered were grouped in classes of 75 m (246 ft). The results obtained are given in Table 3. For example, in the north-south direction, for a nominal distance of 37.50 m (123 ft), 11 pairs of samples were retained. The average distance between these samples was 59.32 m (194.69 ft) in direction north 1.8° west. The calculated value of the semivariogram was 14.59. These results are plotted in Figs. 19 and 20. Fig. 19 is a plot of $\gamma(h)$ as a function of the distance h . It shows that the lowest level of variability is in the north direction, while the highest level of variability is in the east or northwest direction. In all directions, the semivariogram shows first an increase in value followed by a sharp decrease. This could reflect periodicities or symmetry in the distri-

Fig. 18. Cumulative frequency distribution of test case data.

* To convert meters to feet, multiply by 3.281.

bution of the sample values. Symmetry is clearly visible in Fig. 17 and the semivariogram reflects the shape of the high grade central zone apparent on this figure.

To determine the direction of best continuity, it is often helpful to plot the semivariogram in the form of isovariogram curves (Fig. 20). These curves show the distance at which the semivariogram is expected to reach a given value in a given direction. The isovariogram curves are elongated in the direction showing the best continuity in mineralization.

In the test case under study, the best direction of continuity is approximately north 25° east, and the worst direction north 65° west. Additional semivariograms have therefore been calculated in these directions, also with a tolerance angle of 22.5° and distance classes of 75 m (246 ft). The results obtained are given in Fig. 21. This figure also

shows a model that was used to represent the semivariogram, derivation of which will be discussed later. The least variability again appears in the north 25° east direction that corresponds to the axis of the ore shoot. The highest level of variability is in the direction north 65° west. The bell shape shown by the semivariogram in the latter direction reflects the presence of an ore zone approximately 200 m (656 ft) wide with low-grade material on both sides.

Three-Dimensional—Consider now a large porphyry copper ore body sampled by 200 vertical drill holes. Typically, if the deposit is to be mined using 12-m (40-ft) benches, the samples will be grouped in 12-m (40-ft) long composites. Within reasonably homogenous geological environments, an average downhole semivariogram will be calculated using the one-dimensional approach discussed earlier. Also, horizontal

Fig. 19. Directional semivariograms in test case ore body—one-dimensional representation.

Fig. 20. Directional semivariogram in test case ore body—two-dimensional representation.

Fig. 21. Calculated semivariogram and fitted model in principal directions—test case ore body.

semivariograms will be calculated within each bench and averaged between benches. In such a case this preliminary semivariogram study will be used to determine the direction of best continuity in the horizontal plane and to compare the horizontal and vertical directions. The results obtained may be useful in the development of exploration drilling, mine design, and grade control strategies. Unfortunately, a semivariogram study that considers only horizontal and vertical directions is not based on any geological foundation and can lead to incorrect conclusions. Except for a small number of significant exceptions, geological controls have no reason to be preferentially directed in a horizontal fashion.

The method most commonly used to calculate semivariograms in a three-dimensional environment is based on a

conical search (Fig. 22a). The direction of interest is defined by an azimuth and dip. A tolerance angle is specified around this direction and the pairs of samples are grouped according to distance. The directions to be considered are chosen taking known geologic controls on the mineralization into account, wherever possible. The conical search is particularly helpful in large disseminated deposits, such as porphyries. Its main drawback, however, is that it usually requires considerable computer resources. It is also poorly adapted to the analysis of stratified, bedded, or fault-related deposits, or any type of deposit in which the controls of mineralization are essentially planar. For example, consider an ore body whose economic mineralization is fracture controlled and the major fracture zones are striking east and dipping 60° north. The directions

Fig. 22. Three-dimensional search.

to be considered will be (1) one direction normal to the fracture plane orientation, i.e., dipping 30° south, and (2) a number of directions within the fracture plane.

The anisotropy of the semivariogram will then be defined by three principal directions:

- 1) The direction of best continuity that would normally correspond to the plunge direction within the fracture plane orientation.
- 2) The direction normal to plunge within the fracture plane.
- 3) The direction of least continuity which is typically normal to the fracture plane.

A method of semivariogram calculation particularly well adapted to the analysis of mineralization with planar controls is the "slice" window search illustrated in Fig. 22b. The method initially involves preparation of the data so as to assign the bench composites to parallel artificial slices through the deposit, whose strike and dip is user-controlled and is chosen as a function of the known geology. The semivariogram is then calculated within these inclined slices. The technique has the advantage of involving minimal computer time compared with the conical search.

This approach is only applicable to mineralization with

planar control. If there is only a limited geologic understanding of the deposit and the direction of the ore shoots is unknown, one can calculate the bench semivariogram in three perpendicular planes (horizontal, vertical east-west, and vertical north-south). A model of a semivariogram is then fitted in each plane. These planar models are then combined to obtain a three-dimensional mathematical representation that can be used to determine the likely principal directions of continuity (Rendu, 1983). Clearly, this approach should be used in last recourse, and only if geologic understanding is minimal.

An example of three-dimensional anisotropic semivariogram obtained in a massive sulfide deposit with well defined geologic controls is shown in Fig. 23. Semivariogram models are shown in this figure whose derivation is discussed in the next section.

Semivariogram Modeling: Once a semivariogram has been calculated, it must be interpreted by fitting to it a mathematical formula or "model" that will help to identify the characteristics of the deposit and yield numerical parameters that describe the deposit's continuity. Examples of such models are shown in Fig. 24. To the practiced eye, each model has a particular significance.

Fig. 23. Three-dimensional anisotropy in massive sulfide deposit.

GENERAL MODEL

INDIVIDUAL MODELS

Fig. 24. Models of semivariograms.

The “general model” in Fig. 24 shows the main parameters derived from a semivariogram model, namely:

1) The *sill* that shows the highest level of variability measured by the semivariogram. Some semivariograms do not have a sill. If a sill exists, its value is usually close to but higher than the sample variance.

2) The *range* is the distance at which the semivariogram plateaus or reaches the sill value and represents a measure of the maximum distance of influence of a drill hole in the direction concerned. Beyond this distance, sample values are independent of one another. Some semivariograms do not have a range.

3) The *nugget effect* is the value of the semivariogram at zero distance. It represents the sample variability at small distance caused by small-scale geologic controls. It also gives an important indication of the presence and magnitude of sampling and assaying errors.

The most common single model is the *spherical model* that has the equation:

$$\gamma(h) = N + C \left(\frac{3}{2} \frac{h}{a} - \frac{1}{2} \frac{h^3}{a^3} \right) \text{ for } h \leq a$$

$$\gamma(h) = N + C \quad \text{for } h > a$$

where C is the sill, N is the nugget effect, a is the range, and h is the distance lag.

Other models which are commonly found include (Fig. 24):

1) The exponential model that does not have a range but reaches a sill asymptotically.

2) The parabolic model that indicates a linear drift or trend and a high level of continuity in the sample values. It will be observed if there is a systematic linear increase or decrease in values.

3) The gaussian model that behaves like the parabolic model for short distances but plateaus at large distances.

4) The linear model that indicates that the variability is directly proportional to the distance.

5) The “hole effect” model that may be indicative of periodicities in the mineralization, or may only reflect the sample spacing.

In addition, the *de Wijsian model* should be mentioned, as it has great historical significance as the first semivariogram model recognized (Matheron, 1962; Krige, 1978). Its mathematical equation is $\gamma(h) = N + 3\alpha \ln(h)$ where α is a constant and the other variables are as previously defined.

Most semivariograms can be represented by the sum of

a number of submodels, including a nugget effect, a short-range submodel, and a long-range submodel. With the exception of the parabolic, gaussian and hole-effect models, a combination of spherical submodels can be used to represent most other calculated or so called experimental semivariograms.

The *parabolic model* has equation:

$$\gamma(h) = N + \frac{d^2}{2} h^2$$

If the distance between samples is measured in meters, this equation indicates a linear drift in the direction under study; the sample values increasing or decreasing by an amount equal to d units per meter. Parabolic models are commonly observed when highly continuous variables are studied, such as vein or seam thicknesses. They also result when systematic increases or decreases in grade occur, as illustrated by the downhole semivariogram in the supergene sulfide mineralization of a porphyry copper deposit (Fig. 25).

The *gaussian model* is also indicative of a local drift, but over a shorter distance than the one indicated by the parabolic semivariogram. The equation of the gaussian model is:

$$\gamma(h) = N + C [1 - \exp(-h^2/a^2)]$$

For short distances less than $a/2$, the model indicates that the sample values tend to increase or decrease by an amount equal to d units per meter, where:

$$d^2 = 2C/a^2$$

A gaussian model with nugget effect was used to represent the semivariogram of a coal seam shown in Fig. 26. The

Fig. 25. Down hole semivariograms in porphyry copper deposit.

nugget effect has value of 0.8 and in the north-south direction, the gaussian model has sill $C = 8.0$ and range $a = 1800$ m (5906 ft). The model indicates a regular change in thickness in this direction of $d = 2.22$ m per 1000 m (7.3 ft per 3281 ft).

A number of equations have been proposed for semivariograms which present a *hole effect*. One possible equation is:

$$\gamma(h) = N + C \left[1 - \exp\left(\frac{-h}{a}\right) \cdot \cos\left(2\pi \cdot \frac{h}{b}\right) \right]$$

Fig. 26. Semivariogram of coal thickness.

This semivariogram can be used to represent periodicities in sample values, the average distance between high-grade zones being equal to b . Fig. 27 shows the semivariogram obtained in a fracture-controlled deposit with a number of vertical fracture zones oriented in a north-south direction, the distance between zones being approximately 240 m (787 ft). The fitted model in this case is:

$$\gamma(h) = N + C_1 \gamma_1(h) + C_2 \gamma_2(h)$$

where $N = 0.30$, $C_1 = 0.23$, and $C_2 = 0.17$. In the direction of the fracture zones, two *exponential* submodels were used:

$$\gamma_1(h) = 1 - \exp(-h/40)$$

$$\gamma_2(h) = 1 - \exp(-h/600)$$

In the direction normal to the fracture zones, the sum of an exponential and a hole effect submodel was used:

$$\gamma_1(h) = 1 - \exp(-h/15)$$

$$\gamma_2(h) = 1 - \exp(-h/1150) \cos 2\pi(h/240)$$

The first submodel $\gamma_1(h)$ represents the short-range continuity that is clearly much better in the direction of the fracture zones. The second submodel $\gamma_2(h)$ represents the long-range variability and indicates that the average distance between fracture zones is 240 m (787 ft). If drilling is intended to discover new fracture zones for exploration purposes, the optimal drill-hole spacing in the east-west direction is 240 m (787 ft). An equal or larger spacing can be used in the north-south direction. On the other hand, if drilling is intended for grade control and mine planning, the spacing between holes should reflect the short-range variability, with a possible spacing of 40 m (131 ft) in the direction of the ore zones and 15 m (49 ft) in the perpendicular direction.

As illustrated in the previous example in two- or three-dimensional environments, different semivariogram models may be applicable depending on the direction considered, thus reflecting anisotropies or changes in continuity in the mineralization. Two types of anisotropies can be found, depending on the geologic environment considered. *Zonal anisotropies* are observed in bedded or stratabound deposits. The variability within a stratum may be low and remain low for very large distances, while the variability between strata may be much larger, even at short distances. The semivariograms will then have different sills, depending on the directions considered. If the strata are horizontal, a model that may be applicable is:

$$\gamma(h) = \gamma_1(x, y) + \gamma_2(z)$$

where x , y , and z represent the easting, northing, and vertical components of the distance h between samples.

A more common form of anisotropy is the *geometric anisotropy*. If such an anisotropy is present, the sill remains the same in all directions, but the range is variable. Often the range in any direction can be represented by the radius of an ellipse or ellipsoid. For example, consider a deposit with ore zones elongated in the north 60° east direction (azimuth $\alpha_0 = 60^\circ$); the semivariogram being spherical with range $a = 600$ m (1969 ft) in this direction and $b = 400$ m (1312 ft) in the perpendicular north 30° west direction. The range d of the semivariogram in any direction with azimuth α will be calculated as follows:

$$d = \sqrt{1 / \left(\frac{\cos^2(\alpha - \alpha_0)}{a^2} + \frac{\sin^2(\alpha - \alpha_0)}{b^2} \right)}$$

If nested structures are present, neither the direction nor the ratio of anisotropy need be the same for each structure. An example is illustrated in Fig. 28. Structures "en echelon" are clearly visible, the ore pods being oriented in a roughly north 20° south direction while the mineralized areas containing these pods are elongated in a north-south direction. If only a one dimensional representation of the semivariogram had been used (Fig. 29) the different structures would not have been detected.

In most deposits, the sampling density will be such that the short-range variability, including the nugget effect, will be difficult to estimate. In three-dimensional bodies, such as porphyry deposits, the nugget effect can be determined using the downhole semivariogram. In many instances, some limited close spaced drilling will be required to determine the short-range variability in the deposit. A cross of drill holes may be drilled in a "typical" section of the deposit for this purpose. The location and orientation of the lines of holes, and the drill hole spacing along these lines, should be determined taking local geologic factors into account.

Practical Considerations: As for all statistical studies, the semivariogram analysis will give meaningful results only if a number of so called *stationarity* constraints are satisfied. Stationarity first means geological homogeneity. In a porphyry copper deposit for example, a sulfide zone should not be mixed with an oxide zone. The mineralization may differ with rock type as well as with the intensity of that mineralization. Calculation of semivariograms across geologic

Fig. 27. Horizontal semivariograms in a fracture controlled precious metal deposit.

Fig. 28. Two-dimensional representation of semivariogram.

boundaries will give meaningless results. The significance of geologic discontinuities such as faults on the semivariogram should be obvious. Fig. 25 shows the semivariograms obtained in three different geologic environments in a porphyry copper deposit. Fig. 30 illustrates the influence of changes in average grade on the semivariogram in different sections of a precious metal deposit.

A geostatistical study should first start with a thorough review of all geological information concerning the deposit, including rock types, folding, faulting, zones of primary and secondary enrichment, and a model of the genesis of the deposit if available. In most situations, mixing of geologic environments will result in meaningless or erroneous geostatistical results.

The influence of the sample or support size on the semivariogram is similar to the influence of sample size on the sample variance: the larger the sample size, the lower the sample variability. This is illustrated in Fig. 31 where the semivariograms of 2- and 4-m (6.7- and 13-ft) composites are compared. The decrease in variability is known under the name of *regularization* and can be calculated from the semivariogram model. If $\gamma(h)$ is the semivariogram for very small samples and $\gamma_w(h)$ the semivariogram for samples of size $w = 4$ m (13 ft), it can be shown that $\gamma_w(h) = \bar{\gamma}(w; w+h)$

— $\bar{\gamma}(w; w)$ where the quantities $\bar{\gamma}(w; w+h)$ and $\bar{\gamma}(w; w)$ are a function of the sample size w , the distance h , and the semivariogram $\gamma(h)$ (Rendu, 1981). This mathematical relationship can be extremely useful to verify a semivariogram model. The difference between the semivariogram $\gamma_w(h)$ for small samples of size w and the semivariogram $\gamma_W(h)$ for large samples of size W , is approximately equal to:

$$\gamma_w(h) - \gamma_W(h) = \bar{\gamma}(W; W) - \bar{\gamma}(w; w)$$

This relationship is also used to determine the likely effect of different selective mining methods on the grade tonnage relationship. If σ_w^2 is the sample variance and σ_W^2 is the block variance, the difference between variances can be calculated by the same formula:

Fig. 29. One-dimensional representation of semivariogram.

Fig. 30. Logarithmic semivariograms in two zones of a precious metal deposit.

Fig. 31. Influence of sample size on the semivariogram.

$$\sigma_w^2 - \sigma_w^2 = \bar{\gamma}(W; W) - \bar{\gamma}(w; w)$$

The use of this formula will be discussed later.

Differences in sampling methods will also result in differences in the semivariogram. In Fig. 32 the results obtained in a tin deposit are illustrated. Two types of samples were analyzed, core samples and bulk samples taken from successive rounds along horizontal drifts. The semivariograms shown in Fig. 33 represent the properties of the thickness of a precious metal vein deposit, as measured by drilling and

by underground channel sampling. Clearly, if different sampling methods were used to analyze a deposit, the values obtained should be analyzed separately.

Another source of difficulty that is common in the calculation of the semivariogram is the lack of its *stationarity*. Even though the area under study may appear geologically homogeneous, the semivariogram may change significantly throughout the area. The most commonly observed lack of stationarity is caused by a *proportional effect*: the high-grade areas tend to have a higher variability than the low-grade areas. This is illustrated in Fig. 30. A measure of the proportional effect is obtained by comparing the sample variance σ^2 and sample mean \bar{x} in different parts of the deposit (Fig. 34). A relationship of the form:

$$\sigma^2 = K \bar{x}^2$$

where K is a constant, is often observed. It is characteristic of deposits in which the sample values are lognormally distributed. Ignoring the proportional effect when it is present will result in meaningless semivariograms. A number of methods are used to take into account the proportional effect, the applicability of which will vary depending on the deposit under study. These methods include:

1) Division of the deposit into "grade zones" or zones of fairly uniform grade, within which the proportional effect can be ignored.

2) Calculation of a relative semivariogram. The relative semivariogram is $\gamma(h)/\bar{x}^2$ where \bar{x} is the mean value of the samples used to calculate each point of the semivariogram $\gamma(h)$.

3) Calculation of the logarithmic semivariogram. If the sample values are approximately lognormally distributed, the semivariogram of the natural logarithms of the sample values will be independent of the sample grade.

Fig. 32. Comparison of semivariograms in a tin deposit.

Fig. 33. Comparison of diamond drill hole and channel sample semivariograms in a silver vein deposit.

Fig. 34. Proportional effect in a uranium deposit.

Fig. 35 shows the average downhole semivariogram calculated in a precious metal deposit, first using untransformed sample values, then using the logarithm of the sample values. This figure dramatically illustrates the impact of the logarithmic transformation of the data prior to semivariogram estimation.

Some Applications of the Semivariogram: The semivariogram study is one of the most important parts of any geostatistical study. The semivariogram is a prerequisite to the use of the kriging method of ore reserve evaluation. In addition, the semivariogram may supply information concerning:

- 1) The direction of best continuity in the mineralization.
- 2) The orientation and size of high-grade pods.
- 3) The average spacing between ore zones and periodicities in the mineralization.
- 4) The strike and dip of fracture zones and the plunge of the mineralization within these zones.
- 5) The distance of influence of a sample or the distance beyond which the similarity between values is negligible.
- 6) The precision with which the mineralization is known at the point where it is sampled.

Using this information, answers can be given to some critical questions such as:

Fig. 35. Comparison of semivariogram of sample values with logarithmic semivariogram.

- 1) What is the optimal drill hole orientation and drill hole spacing required to complete a drilling program?
- 2) What will be the effect of a highly selective mining method, as opposed to a large scale bulk mining method, on the tonnages and grades mined?
- 3) What sampling method, including sample spacing, should be used for grade control during production?

Hypotheses concerning the genesis of the ore body can be tested and conclusions can be drawn concerning future drilling to find new deposits in the same district or new ore zones in the same deposit.

In summary, there are very few deposits where the process of exploration and evaluation cannot be enhanced through semivariogram analyses. In addition to an improved understanding of the geology of the deposit such analysis provides a quantitative model of the variability of the mineralization that can be directly used as a basis for subsequent reserve calculations.

DISPERSION VARIANCE AND GRADE TONNAGE CURVE

Introduction

Some degree of mining selectivity is adopted in the exploitation of most mineral deposits. The economic value of a deposit is only in part a function of the total tonnage of

material in the deposit and its average grade. More important is the tonnage and average grade of mill feed, or that portion of the deposit that can be economically and selectively mined above a specified cutoff grade and delivered to a mineral processing facility.

Recoverable ore reserves are a function of a number of factors. If selective mining is to be adopted so as to minimize dilution, the size of the smallest block or panel that can be mined selectively as ore or waste must be specified. This block or panel is defined as the *selective mining unit*. If known, the frequency distribution of the values of all the selective mining units in a mineral deposit would supply valuable information. Indeed, consider a porphyry copper deposit whose main mineralized zone represents 100,000,000 tons (110,231,100 st) averaging 1.0% Cu. Assume that the deposit is considered for selective mining with 20-m (65.6-ft) benches, the minimum horizontal block size being 40×40 m (131×131 ft). If the frequency distribution of the selective mining units was known we could determine, for example, that 46% of the deposit, or 46,000,000 tons (50,706,306 st) exceeds a 0.8% Cu cutoff and that the average grade above this cutoff is 1.63% Cu. These tonnages and grades would then be recoverable if two constraints were satisfied:

- 1) Perfect information will be available concerning the average grade of each selective mining unit at the time it is mined. All blocks estimated as ore will be mined and treated as ore. All waste blocks will be treated as waste. In practice, this condition is never satisfied. Blocks are estimated from limited information such as drill holes, blastholes, or channel samples. Errors will be made that will result in differences in both tonnage and grade.

- 2) All blocks exceeding the cutoff grade can be accessed and mined at a profit. Again, this condition is rarely satisfied.

Nevertheless, knowledge of the total ore tonnage and corresponding average grade above a given cutoff grade is of great economic significance if it can be determined early in the evaluation of a deposit. Also very significant would be a knowledge of the relationship between grade and tonnage as a function of cutoff grade and of the degree of selectivity with which the deposit will be mined.

Geostatistical methods are available to estimate the frequency distribution of the selective mining units using both the frequency distribution of the sample values and the semivariogram. The precision with which the value of the selective mining units will be known, when estimated from blastholes, can also be taken into account. These geostatistical methods give only global estimates, independent of geometric mining constraints. Other methods, including kriging, the geostatistical ore reserve evaluation technique, are used for local estimation as needed for mine planning, grade control and selective exploitation. Kriging will be discussed later.

The dispersion variance concept introduced in this section is useful early in a deposit evaluation cycle when limited data is available. This concept is also another building block in the understanding of kriging. Detailed discussions on mining selectivity and the estimation of recoverable reserves at a local level are given later.

Mathematical Equations

The geostatistical methods for estimating the frequency distribution of selective mining units are based on two premises:

- 1) Conservation of the frequency distribution: if the sample values are normally distributed, the block values will also be normally distributed (conservation of normality). If the

sample values are lognormally distributed, so will be the block values (conservation of lognormality).

2) The variance of the block values in the deposit can be calculated from the variance of the sample values and the semivariogram, or from the variance-volume relationship to be discussed later.

The validity of these premises has been proven theoretically for the normal distribution and has been tested extensively using results obtained in various deposits.

The best known relationship between grade and tonnage is probably Lasky's relationship (Lasky, 1950):

$$g_{+c} = a - b \ln(T_{+c})$$

where g_{+c} is the average grade above cutoff grade, T_{+c} is the tonnage above cutoff grade, and a and b are coefficients that vary with both the deposit and the mining method.

This relationship can be derived from the lognormal theory and has been observed in many deposits, from porphyry copper to disseminated gold. The values of the coefficients a and b are a function of the variability of the ore in the deposit and of the degree of selectivity with which it will be mined. They usually have to be determined empirically, using historical data. If geostatistics is used, on the other hand, the relationship between tonnage and grade can be determined early in the study of a deposit, using the sample values. The average grade μ of the deposit can be calculated from the sample values. The dispersion variance of the block values σ_w^2 can also be determined from the variance or the semivariogram of the sample values.

Normal Distribution: If the sample values are normally distributed, then the block values are also normally distributed with mean μ and variance σ_w^2 . The tonnage of ore above a given cutoff x_c is given as a function of the total tonnage T , and is estimated by the following formula:

$$\frac{T_{+c}}{T} = F(y)$$

where

$$y = (x_c - \mu)/\sigma_w$$

and

$$F(y) = \frac{1}{\sqrt{2\pi}} \int_y^{+\infty} \exp(-t^2/2) dt$$

The average grade of this ore material is calculated as follows:

$$\frac{\mu_{+c}}{\mu} = 1 + \frac{1}{\sqrt{2\pi}} \cdot \frac{\sigma_w}{\mu} \exp(-y^2/2) / F(y)$$

The value of the F function can be obtained from statistical tables of the cumulative normal distribution. Graphical methods can be used to calculate the tonnages and grades above cutoff grade (Fig. 36). The foregoing equations are also easily programmed on a pocket calculator. As an example, consider a bedded deposit, with average thickness of 5 m (16 ft). The variance of the thickness of 50 × 50-m (164 × 164-ft) panels has been estimated at 4 m² (43 sq ft). Assuming a normal distribution, it can be calculated that 84% of the deposit will have a thickness in excess of 3 m (9.8 ft) and will average 5.60 m (18 ft). How the variance of these 50 × 50-m (164 × 164-ft) panels can be calculated will be discussed in the next section.

These results could have been obtained graphically, using Fig. 36. We calculate: block mean to be 5 m (16.4 ft) and block standard deviation to be $\sqrt{4}$ equals 2 m (6.6 ft).

$$X = (\text{cutoff-mean})/(\text{standard deviation}) = (3.5)/2 = -1$$

Fig. 36. Determination of tonnage-grade relationship, normal distribution.

Using the horizontal axis we see that indeed approximately 84% of the total tonnage is expected to exceed the cutoff grade. Furthermore:

$$Y = (\text{standard deviation})/(\text{mean}) = 2/5 = 0.4$$

Using these values of X and Y the following ratio is estimated graphically:

$$(\text{average above cutoff})/(\text{mean}) = 1.12$$

The average thickness above cutoff is therefore expected to be 12% above the mean, or $1.12 \times 5 = 5.60$ m (18 ft).

Lognormal Distribution: For all practical purposes, if the sample values are lognormally distributed, the distribution of the block values will also be lognormal. Even though not mathematically proven, this theorem, known as conservation of lognormality, has been fully verified in numerous deposits.

If the mean value of the deposit is μ and the logarithmic variance of the block values is σ_{ew}^2 , then the tonnage and average grade above cutoff grade will be calculated as follows:

$$\frac{T_{+c}}{T} = F \left[\frac{1}{\sigma_{ew}} \ln \left(\frac{x_c}{\mu} \right) + \frac{\sigma_{ew}}{2} \right]$$

$$\frac{\mu_{+c}}{\mu} = F \left[\frac{1}{\sigma_{ew}} \ln \left(\frac{x_c}{\mu} \right) - \frac{\sigma_{ew}}{2} \right] / F \left[\frac{1}{\sigma_{ew}} \ln \left(\frac{x_c}{\mu} \right) + \frac{\sigma_{ew}}{2} \right]$$

Again, a graphical method can be used to calculate these tonnages and grades (Fig. 37). These formulae are also easily programmable on a pocket calculator. If a copper deposit has average grade 1.0% Cu and the logarithmic variance of $40 \times 40 \times 20$ -m ($131 \times 131 \times 65.6$ -ft) blocks is 0.6, the tonnage of ore above a 0.8% Cu cutoff grade is 46% of the total tonnage in the deposit and it averages 1.63% Cu. If a reduced level of mining selectivity is applied with blocks of size $50 \times 50 \times 25$ m ($164 \times 164 \times 82$ ft), the logarithmic variance will be reduced, possibly to a value of 0.5. Then 48.5% of the total tonnage will exceed 0.8% Cu, with an average grade of 1.54% Cu.

To obtain these results graphically, the ratio (cutoff)/(mean) = 0.8 is read along the vertical axis in Fig. 37. Given a logarithmic variance of 0.6, the following ratios can be estimated:

$$(\text{tonnage above cutoff})/(\text{total tonnage}) = 46\%$$

$$(\text{average grade above cutoff})/(\text{mean}) = 1.63$$

Fig. 37. Determination of tonnage-grade relationship, lognormal distribution.

The influence of selectivity on the grade-tonnage relationship is illustrated in Fig. 38 for a gold deposit. When the selectivity decreases and the smallest block size that can be mined selectively increases, the average grade above cutoff grade decreases. At the same time, except possibly for very high cutoff grades, the tonnage above the cutoff grade increases.

Comparison between a tin and a molybdenum deposit is shown in Fig. 39. In the tin deposit, most of the variability

Fig. 38. Influence of selectivity on grade tonnage relationship.

LOGARITHMIC SEMIVARIOGRAMS

BLOCK SIZE (FEET)	TIN DEPOSIT		MOLYBDENUM DEPOSIT	
	1,000,000 TONS AT 0.1 % Sn CUT OFF GRADE 0.07% Sn		1,000,000 TONS AT 0.1 % MoS ₂ CUT OFF GRADE 0.07% MoS ₂	
	TONNAGE ABOVE CUT OFF (TONS)	AVERAGE GRADE ABOVE CUT OFF (% Sn)	TONNAGE ABOVE CUT OFF (TONS)	AVERAGE GRADE ABOVE CUT OFF (% MoS ₂)

50x50x50	580,000	0.14	700,000	0.12

TONNAGE - GRADE RELATIONSHIP

Fig. 39. Influence of semivariogram on grade tonnage relationship.

in grade occurs over short distances, approximately 20 m (65.6 ft), while the grade is less variable and relatively continuous over much larger distances in the molybdenum deposit. Increasing the selectivity by reducing the block size from 20-m (65.6-ft) cubes to 4-m (13-ft) cubes results in a 21% increase in grade and an 18% decrease in tonnage in the tin deposit. The same increase in selectivity has a much smaller effect on the molybdenum deposit, the grade increasing by only 8% and the tonnage decreasing by 4%. These results are directly derived from the semivariogram and illustrate the fact that the impact of mining selectivity is more pronounced as the variability of the economic mineral in the deposit increases.

Dispersion Variance, Variance-Volume, and Variance Additivity Relationship

Earlier, we looked at the distribution of the sample values and calculated the mean value and the variance of these values. By definition, the sample variance calculated in a given area is the *dispersion variance* of the samples in the area. There are two variances of interest to the geostatistician, the dispersion variance, to be discussed here, and the estimation or error variance that will be analyzed later.

If, instead of considering samples, we consider blocks of a size that can be mined selectively, the mean value of all the blocks within a given area is equal to the mean value of the samples. However, the variability of the block values is less than the variability of the sample values. The block dispersion variance is a decreasing function of the block size. Furthermore the dispersion variance corresponding to a given block size is also a function of the size of the area within which it is calculated. If only a small section of a deposit is considered, either high-grade or low-grade, the block values will have a low variability. If a large section of the deposit is considered, both low-grade and high-grade zones will be represented and the variance would be expected to increase.

The main relationship between variance and size of area is known as the *variance additivity relationship* or Krige's relationship. Consider an ore body O within which samples of size w have been taken. The variance of the sample values in the ore body is equal to the variance of the samples in selective mining units of size W , plus the variance of the selective mining units in the ore body:

$$\sigma_D^2(w \text{ in } O) = \sigma_D^2(w \text{ in } W) + \sigma_D^2(W \text{ in } O)$$

The relationship between the sample (dispersion) variance $\sigma_D^2(w \text{ in } W)$ and the block size W is known as the *variance-area* or *variance-volume* relationship. The larger the block size the larger the variance of the samples within the block. Given the variance-volume relationship, it is possible to calculate the dispersion variance of the block values in the ore body for any block size:

$$\sigma_D^2(W \text{ in } O) = \sigma_D^2(w \text{ in } O) - \sigma_D^2(w \text{ in } W)$$

The variance volume relationship is also sometimes defined as the relationship between the dispersion variance of the block values in the orebody $\sigma_D^2(W \text{ in } O)$ and the block size W . This variance is a decreasing function of the block size.

The variance of samples w in blocks W can be calculated directly from the sample values. For example, the variance of the samples in the ore body is $\sigma_D^2(w \text{ in } O)$. Alternatively, the dispersion variance can be calculated from the semivariogram, in which case the following formula will be used:

$$\sigma_D^2(w \text{ in } W) = \bar{\gamma}(W; W) + N$$

where N is the nugget effect of the semivariogram and $\bar{\gamma}(W; W)$ is the average value of the semivariogram within the block W .

The $\bar{\gamma}$ function can be calculated using either auxiliary functions (known as F functions) and graphs or by numerical integration. The graph reproduced in Fig. 40 can be used to calculate the average value of a spherical semivariogram in a block of size $L \times D$.

To illustrate the use of this graph, consider the test case analyzed earlier (Fig. 17). Twenty-five samples are available in the ore body with mean 18.60 and variance

$$\sigma_D^2(w \text{ in } O) = 30.92$$

For distances less than the range (Fig. 21), the semivariogram is spherical without nugget effect, with a sill $C = 50$ and a range

$$a_1 = 750 \text{ m (2460 ft) in the direction north } 25^\circ \text{ east}$$

$$a_2 = 210 \text{ m (689 ft) in the direction north } 65^\circ \text{ west.}$$

If we want to estimate the dispersion variance of $100 \times 100\text{-m}$ ($328 \times 328\text{-ft}$) blocks, we can use Fig. 40. Since $L/a_1 = 0.133$ and $D/a_2 = 0.476$ we read

$$F(L; D)/C = 0.24$$

hence

$$\begin{aligned} \sigma_D^2(w \text{ in } W) &= \bar{\gamma}(W; W) = F(L; D) \\ &= 50 \times 0.24 = 12.00 \end{aligned}$$

The dispersion variance of the blocks W in the deposit is therefore expected to be:

$$\sigma_D^2(W \text{ in } O) = 30.92 - 12.00 = 18.92$$

The sample values being approximately normally distributed (Fig. 18), we can assume that the block values are also

Fig. 40. Two-dimensional F function for the spherical semivariogram.

normally distributed, with mean 18.60 and variance 18.92. Using the formulae given previously for the normal distribution, we estimate that 37% of the deposit exceeds a 20.00 cutoff with average grade 23.00. Visual analysis of the sample values in Fig. 17 indicates that this result is reasonable.

In many instances, and more specifically when estimating block values by kriging, the *covariogram* $\sigma(h)$ is used rather than the semivariogram. The covariogram is defined as:

$$\sigma(h) = \sigma^2 - \gamma(h)$$

where σ^2 is the variance of the samples in the deposit. Then the block variance is calculated directly:

$$\sigma_b^2(W \text{ in } O) = \bar{\sigma}(W; W)$$

where $\bar{\sigma}(W; W)$ is the average value of $\sigma(h)$ within the block W . This approach is required when the sample values are lognormally distributed and only the logarithmic semivariogram $\gamma_e(h)$ is available. The logarithmic covariogram is:

$$\sigma_e(h) = \sigma_e^2 - \gamma_e(h)$$

where σ_e^2 is the logarithmic variance of the samples in the deposit. The relative semivariogram is $\sigma(h) = \exp[\sigma_e(h)] - 1$ and the relative dispersion variance of the block is equal to $\bar{\sigma}(W; W)$. The logarithmic dispersion variance of the blocks is obtained as:

$$\sigma_{de}^2(W \text{ in } O) = \ln[\bar{\sigma}(W; W) + 1]$$

This is the logarithmic variance that must be used to calculate the grade tonnage relationship for lognormally distributed block values (Fig. 37).

Numerical Calculation of $\bar{\gamma}(W; W)$ or $\bar{\sigma}(W; W)$

By definition $\bar{\gamma}(W; W)$ is equal to the average value of the semivariogram $\gamma(h)$ when all possible pairs of points in the block W are taken into consideration. In this calculation, the nugget effect N must be ignored as its contribution is treated separately in all equations given in this section.

There is an infinite number of points in the block W and an exact calculation of $\bar{\gamma}(W; W)$ would be prohibitively time-consuming even with the fastest computers. A simple approximation method is commonly used, known as discrete representation. The block is divided into a number of small volumes of equal size and a single point is taken within each volume. The value of $\bar{\gamma}(W; W)$ is then estimated as the average value of the semivariogram between these points. As an example, consider a block of size $40 \times 40 \times 15$ m ($131 \times 131 \times 49$ ft). The semivariogram has been calculated using 15-m (49-ft) composites. The model accepted is the sum of a nugget effect $N = 0.2$ and an isotropic spherical model with sill $C = 0.8$ and range $a = 160$ m (525 ft). To calculate $\bar{\gamma}(W; W)$, one could choose to divide the block W into four equal cubes of $40 \times 40 \times 15$ m ($131 \times 131 \times 49$ ft). A first approximation would then be (Fig. 41):

$$\begin{aligned}\bar{\gamma}(W; W) &= [4 \gamma(0) + 8 \gamma(20) + 4 \gamma(20\sqrt{2})]/16 \\ &= (4 \times 0 + 8 \times 0.149 + 4 \times 0.210)/16 \\ &= 0.127\end{aligned}$$

This approximation is poor and in practice it is considered that a 16-point discrete representation is needed to obtain acceptable results (Fig. 41). The corresponding value would be 0.149. If Fig. 40 is used, given $H/a = D/a = 40/160 = 0.25$, we obtain $\bar{\gamma}(W; W) = 0.8 \times 0.195 = 0.156$.

$\bar{\sigma}(W; W)$ can be calculated directly from the covariogram function $\sigma(h)$, using the same method of discrete representation of the block W .

Fig. 41. Estimation of $\bar{\gamma}$ or $\bar{\sigma}$ by discrete representation.

GEOSTATISTICAL RESERVE EVALUATION

Error of Estimation

Definition: When estimating an ore body or part thereof from a number of sample values, an error is inevitably made. It can be very valuable to have some measure of the potential size of this error. Consider a panel in a vein deposit, with 20 m (65.6 ft) along strike and 15 m (49 ft) downdip (Fig. 42). The true average thickness of the vein in this panel and therefore the corresponding tonnage of ore are unknown. Let Z be the unknown average thickness that can be estimated by drilling a hole in the center of the panel. Let Z^* be the thickness measured in this hole, say 10 m (33 ft). By definition, the *variance of estimation* of the panel thickness is the expected mean squared difference between Z and Z^* :

$$\sigma_E^2 = \text{expected value of } (Z - Z^*)^2$$

The square root σ_E of the estimation variance is the standard error of estimation. It is often assumed that the error of estimation is approximately normally distributed. Under this condition there is approximately a 68% probability (two chances in three) that the true average thickness of the vein in the panel is greater than $Z^* - \sigma_E$ and less than $Z^* + \sigma_E$. There is approximately 95% probability (19 chances in 20) that this thickness is greater than $Z^* - 2\sigma_E$ and less than $Z^* + 2\sigma_E$.

The precision that can be attached to any estimate of the average thickness of a vein in a panel will vary, depending not only on the sample information available to estimate it, but also on the method of estimation and the variability of the vein thickness. This variability is quantified by the semivariogram. Although the true thickness of the panel is unknown, the variance of estimation for a particular estimation method can be calculated as a function only of the semivariogram, the location of the samples with respect to the panel, the weight given to each one of the samples, and the size and orientation of the panel.

PANEL TO BE ESTIMATED

DISTANCE (METERS)

SEMIVARIOGRAM
OF THICKNESS

ONE CENTRAL SAMPLE

$$Z^* = 10 \text{ meters}$$

$$\sigma_e = 3.5 \text{ meters}$$

Fig. 42. Error of estimation.

FOUR CORNER SAMPLES

$$Z^* = \frac{6 + 12 + 14 + 8}{4} = 10 \text{ meters}$$

$$\sigma_e = 2.3 \text{ meters}$$

Given the isotropic semivariogram shown in Fig. 40, the precision with which a panel of 20×15 m (65.6×49 ft) would be estimated from a single central sample can be calculated. A standard error of 3.5 m (11.5 ft) is obtained. If the central sample indicated a 10-m (33-ft) thickness, there is 68% probability (two chances in three) that the average thickness of the panel is less than 13.5 m (44 ft) and greater than 6.5 m (21.3 ft).

In the same vein deposit, consider a panel of the same size, 20×15 m (65.6×49 ft), estimated by the arithmetic average of four corner samples. The corresponding standard error is 2.3 m (7.5 ft). If the thicknesses observed at each corner are 6, 12, 14, and 8 m (19.7, 39, 46, and 26 ft), respectively, the average thickness of the vein will be estimated at 10 m (33 ft) with 68% central confidence limits 12.3 and 7.7 m (40.4 and 25.3 ft).

Error of Estimation and Risk Analysis: The error of estimation is useful for estimating the risk involved in opening a new mine. The need for additional drilling can be quantified by comparing the cost of drilling with the expected resulting decrease in the estimation error. The optimal locations of additional drill holes can also be determined as they must be chosen to minimize the resulting error of estimation.

The error of estimation can also be used to determine, on a monthly or yearly basis, the precision with which the properties of the mineral to be produced are known. Confidence limits for critical parameters such as pounds of sulfur per million Btu in a coal seam or bismuth content in a massive sulfide zinc deposit can be obtained. The potential for unacceptable variations in these parameters can be detected and might lead to a decision for additional drilling, a change in

a mining strategy, and/or an increase in storage and blending capacity (Fig. 43).

Error of Estimation and Selective Mining: In most mining operations, some degree of selectivity is applied during mining. Blocks or panels whose estimated value exceeds a specified cutoff grade are processed as ore blocks while blocks estimated below cutoff grade are treated as waste. The decision to classify a block as an ore or waste block is made on the basis of the detailed but incomplete information available at the time mining takes place.

This information, which may include channel samples, exploration drill holes, or assayed blastholes, is usually not sufficient to allow exact calculation of the block values. Consequently some blocks will be estimated as being below cutoff grade whose true grade exceeds the cutoff grade. They will be incorrectly treated as waste blocks. Other blocks will be estimated as being above cutoff grade whose true grade is below cutoff grade. They will be incorrectly treated as ore blocks. This situation is illustrated in Fig. 44. A scatter diagram is shown in which each block is represented by a point, with horizontal coordinate the (known) block estimated value, Z^* , and vertical coordinate the (unknown) block value, Z . Ideally, one would mine only the ore blocks with true value Z exceeding the cutoff grade. In fact, one will mine the blocks whose estimated value Z^* exceeds the cutoff grade.

The scatter diagram is divided in four sectors. The first sector contains ore blocks that will be treated as waste. The second sector contains ore blocks that will be treated as ore. The third sector contains waste blocks that will be treated as ore. The fourth sector contains waste blocks that will be

Fig. 43. Estimation error and quality control.

treated as waste. The number of blocks falling in the first and third sectors should be minimized.

Consider a gold deposit averaging 0.10 oz per ton (Fig. 45). If the polygon method is used to estimate the selective mining units from a single central sample, the following results are likely to be observed (Krige, 1962):

1) If the economic cutoff grade is less than the average grade of the deposit (say 0.05 oz per ton), using this cutoff grade for selective mining will result in a significant tonnage of ore material being treated as waste. Indeed, the tonnage of ore material being mined can be increased by decreasing the effective cutoff grade to a level below the economic cutoff grade. Alternatively, and this is the approach often taken, a "dilution factor" is taken into account, preferably based on past experience, to bring up the value of the low grade blocks that are recognized as being underestimated.

2) If the economic cutoff grade is higher than the average grade of the deposit (say 0.20 oz per ton), most and possibly all the material sent to the mill will average less than the economic cutoff grade. The average grade of the blocks estimated at cutoff grade is significantly less than the cutoff grade. Again, the overestimation of the high grade blocks is usually recognized and a dilution factor is introduced to reduce these block values.

In a selective mining environment, two types of dilution should be taken into account, known as external and internal dilution. The first *external dilution* is caused by limitations in the mining method. It is usually impossible to mine a $15 \times 15 \times 20$ -m ($49 \times 49 \times 65.6$ -ft) block without some dilution from surrounding material. The second, *internal dilution*, is of a completely different origin, as it reflects a weakness in the method of reserve evaluation.

Only if a smoothing method of block estimation such as the kriging method is used will the situation obtained be closer to an ideal situation (Fig. 46), the true average grade of the blocks estimated at cutoff grade being equal to the cutoff grade. If such a method is used, the need for an internal dilution factor may disappear, but external dilution still remains to be accounted for. How to estimate recoverable reserves from the in-situ reserves estimated by kriging is the subject of extensive discussions later in this chapter.

A Case Study Using Cross Validation

To illustrate these problems, a method of analysis known as "cross validation" has been applied to a porphyry copper deposit. A total of 200 drill-hole composites of equal length were available for analysis. Each composite was successively removed from the data set, and the same composite point in

Fig. 44. Error of estimation and selective mining.

LOW ECONOMIC CUT OFF GRADE:
THE EFFECTIVE CUT OFF GRADE SHOULD BE LOWER.

HIGH ECONOMIC CUT OFF GRADE:
THE EFFECTIVE CUT OFF GRADE SHOULD BE HIGHER.

Fig. 45. The polygon method and selective mining.

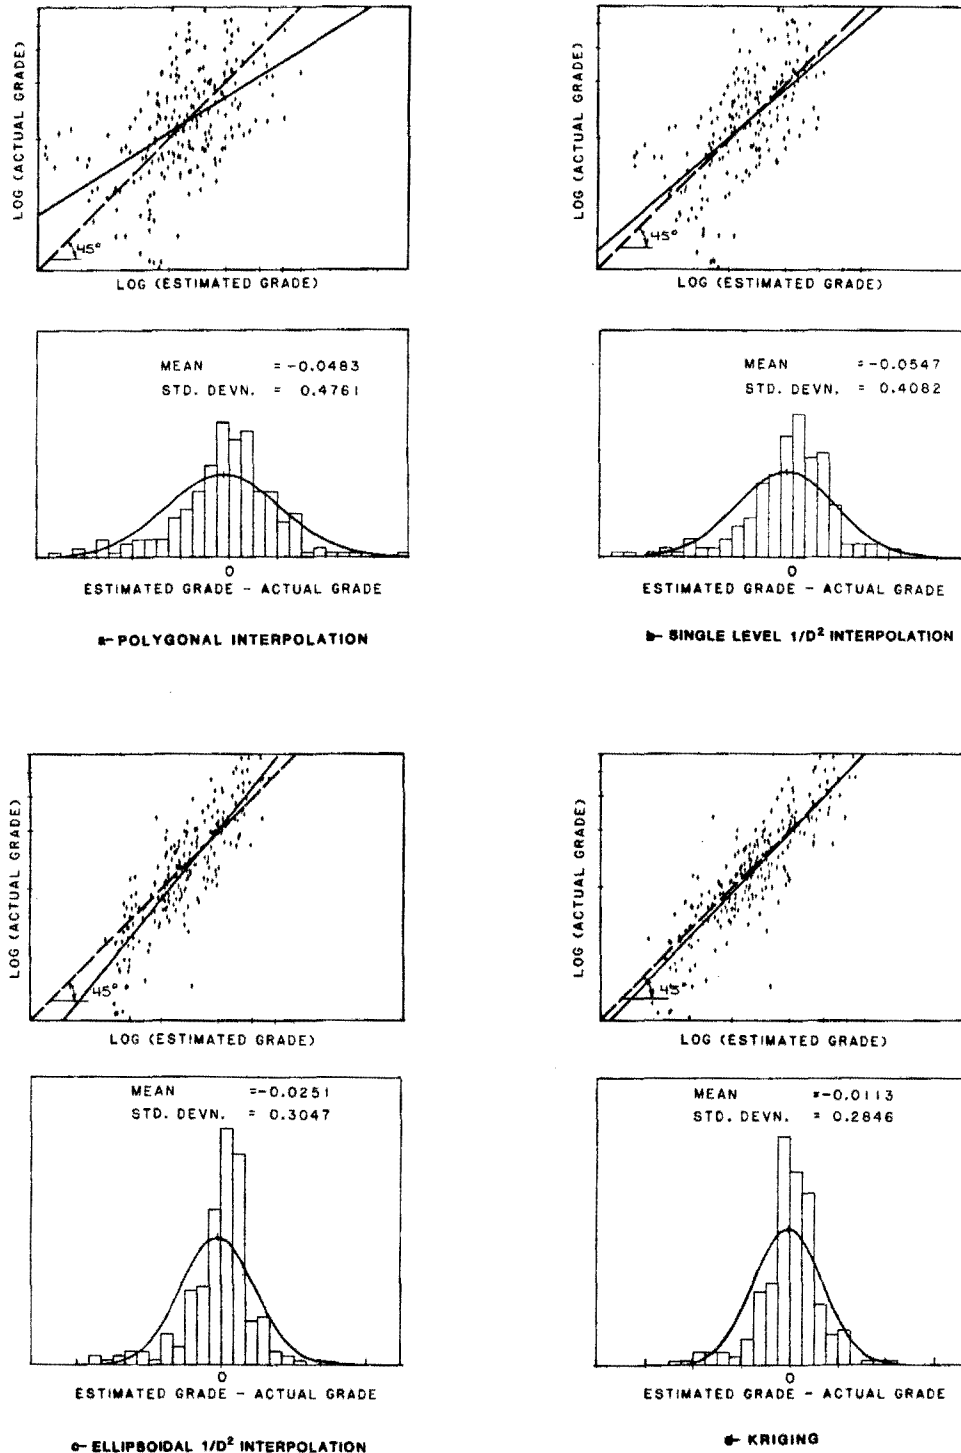

Fig. 46. The Kriging method and selective mining.

the ore body was estimated from surrounding assay values using a variety of methods: nearest sample grade assignment (polygonal approximation), inverse distance square interpolation using both two-dimensional bench search and three-dimensional ellipsoidal search, and finally kriging (Readdy, et al., 1982).

The estimated composite values were then compared with the true assays through the use of linear regression. The most accurate estimation method would be that which yielded a regression line passing closest to the origin with a slope closest to 45° and with minimum variability or scatter about the best fit line. Using geostatistical terminology, this method would best approximate the desirable conditions of minimum error variance along with conditional and local unbiasedness.

For each estimation method, the differences between true assay values and estimated grades were also computed and plotted in the form of a histogram of errors. Once again, the best method would be the one that would have a mean error of zero (global unbiasedness) and the least variance in this error distribution (minimum error variance). Fig. 47 gives the results of these studies for each of the methods examined.

The polygonal method (Fig. 47a), that consists of giving to a block the value of the nearest composite located in the same bench, shows the largest error variance. Considerable local biases are also shown by the significant departure be-

47. Analysis of cross validation results.

tween the regression line and the 45° line. Low values are underestimated, while high values are overestimated.

Both the error variance and the local biases are significantly reduced if the blocks are estimated using a multi-sample smoothing procedure such as the inverse square of the distance method, even when considering only composites within a single bench (Fig. 47b). Further reduction in error variance is obtained by taking into account the composites

in the neighboring benches (Fig. 47c). It is interesting to note that in this case, low-grade blocks are overestimated and high-grade blocks are underestimated. This inversion in local bias results from the inability of the inverse square of the distance method to deal properly with autocorrelations between composite values, the result being excessive smoothing.

As indicated in Fig. 47d, the best results are obtained

when the kriging method is used, for which global bias, local biases, and the error variance are reduced to a minimum. All the results that are expected according to the geostatistical theory have been verified by this cross-validation example. This technique, also known as "jackknifing," can be very useful in comparing the results of using various semi-variogram models and kriging schemes to estimate a deposit. Such analysis is often desirable particularly in the predevelopment stage of a property when close-spaced blasthole data is not available for use in validation of the estimation methodology.

Calculation of Estimation Variance

All traditional methods of reserve evaluation consist in estimating the value of a panel or a block W as a linear combination of surrounding sample values. If n samples are used to estimate the block, its estimated value will be:

$$Z^* = \sum_{i=1}^n b_i x_i$$

where b_i is the weight given to the i th sample. The sum of the weights is equal to 1.0. If the inverse square of the distance method is used for example, and d_i is the distance between the i th sample and the center of the block being estimated, then

$$b_i = K/d_i^2$$

where

$$K = 1/\sum_{i=1}^n (1/d_i^2)$$

The error of estimation of the true block value Z is given in the following equation:

$$\sigma_z^2 = \sigma_w^2 + \sum_{i=1}^n \sum_{j=1}^n b_i b_j \sigma_{ij} - 2 \sum_{i=1}^n b_i \sigma_{iw}$$

where: σ_w^2 is the block variance; when j is not equal to i , σ_{ij} is the covariance between the sample i and the sample j ; when $j = i$, $\sigma_{ij} = \sigma_{ii}$ is the variance of the sample i , and σ_{iw} is the covariance between the sample i and the block W .

The value of these variances and covariances can be calculated directly from the autocovariance function $\sigma(h) = \sigma^2 - \gamma(h)$ where σ^2 is the sample variance and is usually taken equal to the sill of the semi-variogram. The block variance σ_w^2 can be calculated using auxiliary functions or by numerical integration as discussed earlier:

$$\sigma_w^2 = \overline{\sigma(W;W)} = \sigma^2 - \overline{\gamma(W;W)}$$

σ_{ij} is equal to the sample variance σ^2 for $i = j$, and to the covariance $\sigma(h_{ij})$ for $i \neq j$, where h_{ij} is the distance between the two samples. σ_{iw} , also denoted $\overline{\sigma(w_i;W)}$ is equal to the average value of the covariance $\sigma(h)$ when h is the distance between the sample and all possible points in the block W . Auxiliary functions can be used in simple cases. More commonly, numerical integration will be used, that is based on discrete representation of the block W .

As an example, consider a block of size 40 x 40 m (131 x 131 ft) and two samples at a distance of 35 m (115 ft), as shown in Fig. 48. Assume that the semi-variogram can be represented by a nugget effect $N = 1.2$ and a spherical model with sill $C = 2.4$ and range $a = 100$ m (328 ft). Using the F auxiliary function (Fig. 38) we calculate $\overline{\gamma(W;W)} = 0.30C = 0.72$. Hence $\sigma_w^2 = 2.40 - 0.72 = 1.68$. Furthermore: $\sigma_{11} = \sigma_{22} = C + N = 3.60$ and $\sigma_{12} = \sigma(70) = 3.60 - \gamma(70) = 0.29$.

Fig. 48. Calculation of the error of estimation.

The covariances σ_{1w} and σ_{2w} are equal. If a four-point discrete representation is used, we can write:

$$\sigma_{1w} = \frac{1}{4} [2\sigma(\sqrt{(25)^2 + (10)^2}) + 2\sigma(\sqrt{(45)^2 + (10)^2})] = 1.16$$

Typically, a 16-point discrete representation is preferred, from which a value $\sigma_{1w} = 1.15$ is obtained.

If the block was to be estimated by the mean value of the two samples, then $b_1 = b_2 = 1/2$ and:

$$\sigma_z^2 = 1.68 + \frac{1}{4} [2 \times 3.60 + 2 \times 0.29] - 2 \times 1.15 = 1.33$$

Note that, provided the stationarity conditions are satisfied, this error of estimation is dependent on the location of the samples w_1 and w_2 but not on their value.

Kriging

General: Intuitively, when estimating a panel or block of ore, the closer samples should be given more weight than the ones farther away. The directions showing the best continuity should also be considered in assigning a weight to a sample. In addition, the relative position of the drill holes with respect to each other should be taken into account. The size of the block to be estimated is also an important factor. Most important is the fact that the optimal method of reserve estimation should be a function of the specific properties of the deposit or part of the deposit within which the block is located. The geostatistical method of reserve estimation takes all these factors into account (Fig. 49).

As indicated earlier, the precision with which a block is estimated can be quantified using the semi-variogram. The error of estimation is a function of the estimation method or, more specifically, of the weight given to each sample in estimating the block. Instead of calculating the error of estimation that corresponds to a given set of sample weights, it is possible to calculate the weights that will result in the minimum error by solving a system of linear equations, known as the *kriging system*, that makes extensive use of the semi-variogram. The resultant weights then form the basis for estimation of thickness, qualities, grade, etc.

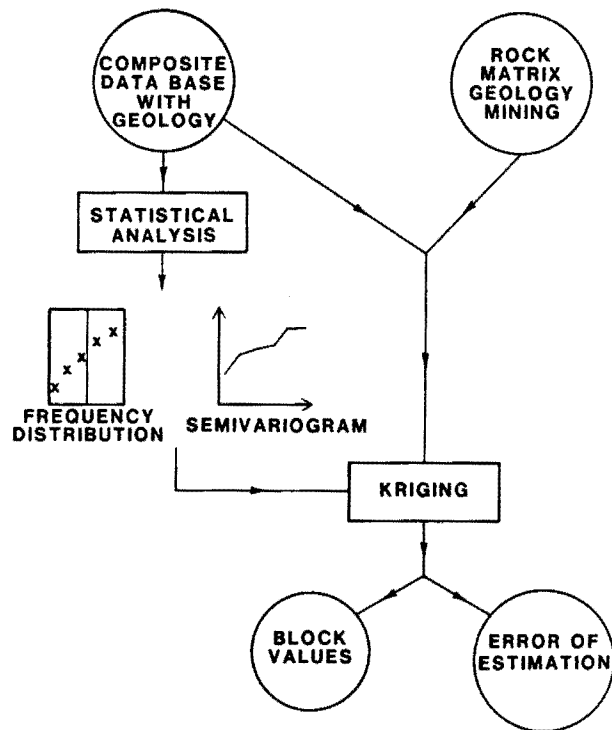

Fig. 49. Geostatistical reserve estimation.

An illustration of a simple kriging problem is given in Fig. 50.

Nine drill-hole intercepts are available within a bench to estimate a block of 122×122 m (400×400 ft). The average grades measured at each hole are shown in Fig. 50 as well as the semivariogram calculated from all the drill holes in the deposit. If the polygon method is used, the block is estimated by the central sample, with value 4% Zn and an error of 1.20% Zn is made. If the mean of the nine samples is used, an average of 6.11% Zn is calculated with an error of 0.72% Zn. If kriging is used, the central sample is given most of the weight and the outside samples are given weights that reflect the anisotropy shown by the semivariogram. The block estimated average grade is 5.10% Zn with an error of estimation of 0.52% Zn.

Kriging can be used to estimate the reserve within an entire deposit, to estimate the reserves scheduled for production on a yearly basis, or to estimate a regular grid of blocks. If a regular grid is estimated, the corresponding errors of estimation can be contoured, as well as the estimated block values. Areas with relatively high errors can be studied with respect to the proposed mining sequence to determine whether additional drilling is required. The block values estimated by kriging can also be used for computerized or manual mine design.

The kriging method of evaluation is the only method that uses to its full potential the statistical and geologic properties of the deposit as represented by the semivariogram. The kriging weights and the error of estimation depend on the block size, block location and sample locations, and on the semivariogram. They are independent of the sample values. This is true only if the necessary stationarity conditions are satisfied.

Another application of the kriging method to estimation of a porphyry copper deposit is illustrated in Fig. 51. In this figure, a block of 15×15 m (50×50 ft) has been estimated from 23 surrounding drill holes. A de Wijsian semivariogram model has been used. The weight given to each sample is shown that can be used to classify the samples according to their influence on the block.

Two rings of samples are observed. In the first ring, comprising four samples, all weights exceed 0.10; the total weight assigned to these four samples is 0.71. In the second ring, comprising nine samples, all weights are below 0.05. Samples outside the second ring have no influence on the block. The results obtained are a function of the distance between the sample and the block, of the sample spacing and of the semivariogram. The samples closest to the block have an influence on the weight assigned to the farther samples. This is known as the *screen effect*. It can be shown that the screen effect is most significant when the semivariogram shows a small nugget effect, while it disappears completely in the presence of a pure nugget effect.

The kriging method of block estimation has been applied to the test data set given in Fig. 17, using the semivariogram model shown in Fig. 21. Blocks of 100×100 m (328×328 ft) have been estimated using the ten samples closest to each block. The results are shown in Fig. 52. All calculations were made on a programmable pocket calculator.

For most ore bodies, block estimation will entail kriging of separate zones (lithologic, structural, etc.) within the deposit, each with its corresponding set of drill-hole data and semivariogram model. It is then necessary to assign a zone identifier to both the drill-hole assay composite data and the three-dimensional block model. A model that portrays the volumetric boundaries between various zones is normally created in advance of kriging and is used to control the block estimation process. Such a model is often referred to as the *geologic model or rock matrix*.

Kriging Calculations: If a block W is estimated from the sample values x_i using a formula of the form:

$$Z^* = \sum_{i=1}^n b_i x_i$$

the error made in estimating the true value Z is a quadratic function of the sample weights b_i . Kriging consists of calculating the weights that should be given to the sample values, so as to minimize the error of estimation. It can be shown (Rendu, 1981) that these weights are obtained by solving the following system of linear equations:

$$\begin{aligned} \sigma_{11}b_1 + \sigma_{12}b_2 + \dots + \sigma_{1n}b_n + \lambda &= \sigma_{1w} \\ \sigma_{12}b_1 + \sigma_{22}b_2 + \dots + \sigma_{2n}b_n + \lambda &= \sigma_{2w} \\ &\vdots \\ \sigma_{1n}b_1 + \sigma_{2n}b_2 + \dots + \sigma_{nn}b_n + \lambda &= \sigma_{nw} \\ b_1 + b_2 + \dots + b_n &= 1 \end{aligned}$$

There are $n + 1$ equations with $n + 1$ unknowns, the sample weights b_i , and the lagrange multiplier λ that must be introduced to impose the constraint that the sum of the weights adds up to 1.0.

This system of equations is known as the *kriging system*. We saw earlier how all the variances and covariances in this system can be calculated from the semivariogram. The optimal weights that are solutions to this system of equations

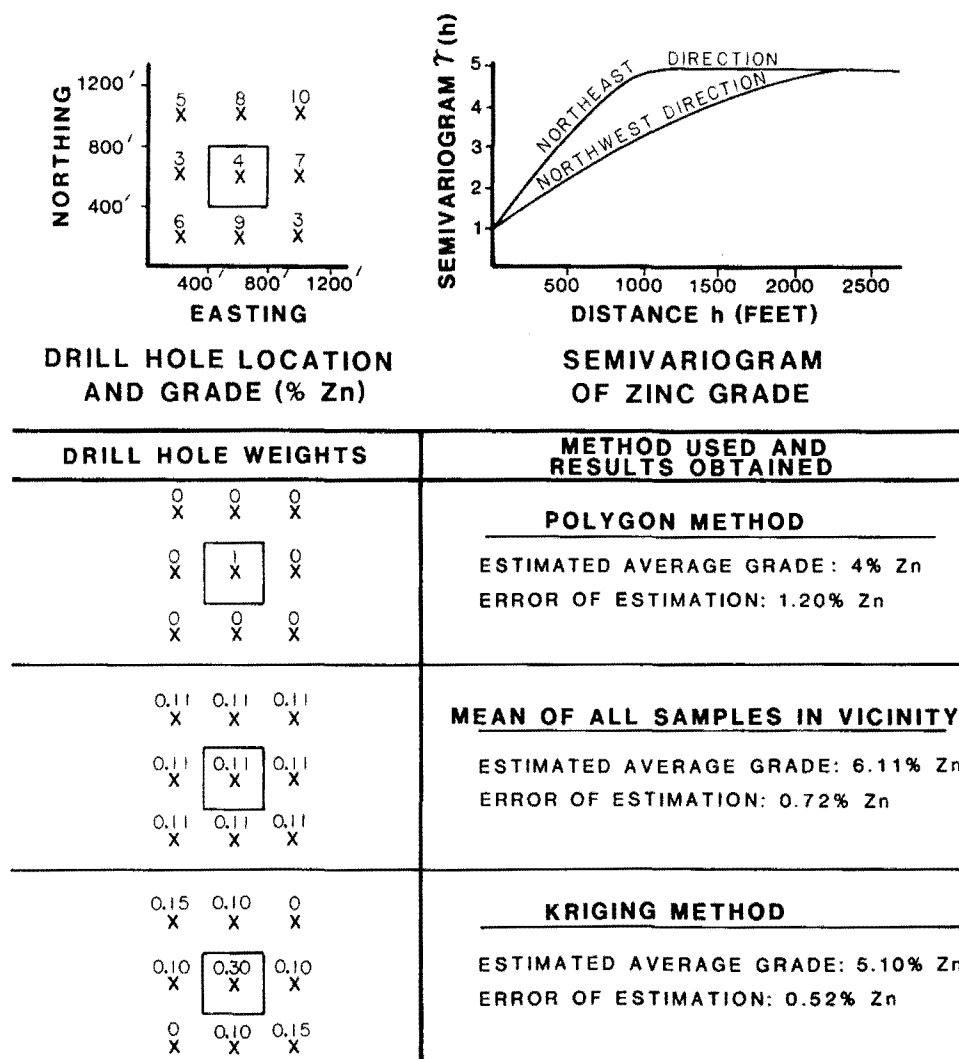

Fig. 50. Comparison of estimation methods.

are the *kriging weights*. The corresponding minimum error of estimation is the *kriging error* and can be written in the following form:

$$\sigma_k^2 = \sigma_w^2 - \sum_{i=1}^n b_i \sigma_{iw} - \lambda$$

As an example, consider the case discussed in "Calculation of Estimation Variance" and illustrated in Fig. 48. Clearly by reason of symmetry, estimation of the block by kriging using only the two samples shown in Fig. 48 can only give the solution $b_1 = b_2 = 0.5$, and an error of estimation as calculated in that section is $\sigma_k^2 = 1.33$. If on the other hand a third sample is considered, in the center of the block, the weight to be given to this and the other two samples must be calculated. Using a 16-point discrete representation of the block when needed, the following variances and covariances are obtained:

$$\begin{aligned} \sigma_w^2 &= 1.68 \\ \sigma_{1w} &= \sigma_{2w} = 1.15 \\ \sigma_{3w} &= 1.87 \\ \sigma_{11} &= \sigma_{22} = \sigma_{33} = 3.60 \end{aligned}$$

$$\sigma_{12} = 0.29$$

$$\sigma_{13} = \sigma_{23} = 1.19$$

Hence the kriging system:

$$\begin{aligned} 3.60 b_1 + 0.29 b_2 + 1.19 b_3 + \lambda &= 1.15 \\ 0.29 b_1 + 3.60 b_2 + 1.19 b_3 + \lambda &= 1.15 \\ 1.19 b_1 + 1.19 b_2 + 3.60 b_3 + \lambda &= 1.87 \\ b_1 + b_2 + b_3 &= 1 \end{aligned}$$

The solution to this system is $b_1 = b_2 = 0.267$, $b_3 = 0.466$, and $\lambda = -0.443$. The corresponding estimation variance is $\sigma_k^2 = 0.638$. If the polygon method was used, only the central sample would be considered and the error of estimation would be $\sigma_e^2 = 1.68 + 3.60 - 2 \times 1.87 = 1.54$.

Some Remarks About the Smoothing Effect of Kriging

According to geostatistical theory and practical experience, if a deposit is mined selectively, the optimal method of evaluation of individual blocks is by kriging. However even if kriging is used, an error will remain in the estimation of the blocks. Consequently the tonnage mined and the cor-

Fig. 51. Kriging and screen effect.

Fig. 52. Estimated block values and estimation errors—test case ore body.

responding average grade will differ from the tonnages and grades that would be mined if we had exact information concerning the true grade distribution.

In the study of the dispersion variance, it was shown that the likely effect of selectivity and cutoff grade can be estimated by assuming a normal or lognormal distribution of the block values with known mean and variance. If we had exact information, the variance to be used would be the variance of the true block values Z . Since we have only limited information, the variance that must be used is the variance of the estimated block values Z^* . This dispersion variance is

$$\sigma_D^2 = \sigma_w^2 - \sigma_K^2 - 2\lambda$$

In most practical applications, λ is negative and small when compared with σ_K^2 . The dispersion variance of the estimated block values is then less than the variance of the true block values. This variance reduction is known as the *smoothing effect* of the kriging procedure.

For example, consider a gold deposit with average grade of 5 g/t (0.18 oz per ton) to be mined selectively by blocks of $20 \times 20 \times 10$ m ($65.6 \times 65.6 \times 32.8$ ft). Using the semivariogram it is possible to estimate the block relative dispersion variance. Assuming that a value $\sigma_w^2 = 1.4$ was obtained and given a cutoff grade of 4 g/t (0.14 oz per ton), we would expect 41% of the deposit to be above cutoff grade, averaging 9.3 g/t (0.33 oz per ton) if we had perfect information. These results were obtained assuming a lognormal distribution of the true block values, with mean 5 g/t (0.18 oz per ton) and logarithmic variance $\ln(1 + 1.4)$. In practice, the block values are estimated from blasthole assays. Assuming that the relative error of estimation of the blocks from these blastholes is $\sigma_K^2 = 0.4$ and ignoring the lagrange multiplier, the relative dispersion variance of the block estimates will be $\sigma_D^2 = 1.4 - 0.4 = 1.0$. Using this dispersion variance we can now expect that 44% of the deposit will be estimated above cutoff, averaging 8.5 g/t (0.3 oz per ton). If the blasthole sampling can be improved to the point where the relative kriging error is reduced to 0.2, the estimated ore tonnage will be 42% of the deposit, at an average grade of 8.9 g/t (0.31 oz per ton), significantly closer to the optimum of 41% at 9.3 g/t (0.33 oz per ton).

Other Geostatistical Methods

In theory, the linear kriging method of reserve estimation discussed in the foregoing is a minimum variance, conditionally unbiased estimator only if minimum stationarity conditions are satisfied and the sample values are normally distributed. If departure from this ideal but unfortunately rather uncommon model occurs, linear kriging still remains the best linear method of estimation but can give conditionally biased results.

Other geostatistical methods have been developed that are applicable under specific circumstances. Logarithmic kriging (Journel and Huijbregts, 1978; Rendu, 1979) was developed to estimate deposits in which the sample values are lognormally distributed. Disjunctive kriging (Matheron, 1976; Rendu, 1980) can be used to estimate deposits within which the sample frequency distribution is well known but cannot be represented by simple models such as the normal or lognormal model. Universal kriging (Journel and Huijbregts, 1978) was developed to estimate block values when drifts are present and the necessary stationarity conditions are no longer satisfied.

Finally, geostatistical methods have been developed to assist in the evaluation of possible grade control, blending,

and short-term mining and processing problems. These methods, known as "ore-body simulation" (Journel and Huijbregts, 1978) are aimed at creating a computer model of the ore body that shows the same short-range variability as is present in the deposit itself. This computer model can then be used to detect problem areas, before exploitation actually begins, possibly resulting in changes in the mining, blending, and/or processing of the ore. Ore-body simulation must not be used for reserve estimation, however.

EVALUATION OF RECOVERABLE RESERVES

Objective

Since the ore reserves of a mining company are its primary asset and represent its potential for economic viability, any mineral property evaluation should include the best possible estimate of ore reserves that are regarded as *economically recoverable*. It is therefore very important to review the implications of the word "recoverable" in the context of this section on statistical and geostatistical methods.

Earlier we have dealt with the available statistical and geostatistical methods for estimating in situ global or geologic reserves. Some discussion has also been given on the estimation of overall deposit tonnages and grades that might be considered recoverable given a certain cutoff grade and mining selectivity. The intention here is to introduce concepts involved in the conversion of an in situ deposit block model and corresponding reserve estimate into one which is considered recoverable in response to a selected mining and mineral processing production stream. The questions of cutoff grade, dilution, mining selectivity, etc., will be covered in more detail than was possible in earlier sections.

Implicit in the recoverable reserve notion is the fact that what is of interest to the mining company is the quantity of metal or valuable constituent that can be recovered and economically sold. It is not the quantity that may exist as an in situ resource or even that which is regarded as minable, i.e., merely contained within certain defined pit limits. We should be interested in properly estimating not only the ore tonnage and grade that will be recovered during mining, but in addition, the metal content that will be recoverable during processing.

To properly arrive at a recoverable reserve estimate the study team, comprising geologists, mining engineers, and metallurgists, should address each of the following interwoven factors:

- 1) *Cutoff grade*, referring to grade above which material is regarded as ore and dispatched to the mill.
- 2) *Mining recovery*, referring to that tonnage and grade on a block by block basis that is expected to be realized in practice given a certain cutoff grade and selectivity in mining the deposit (*recoverable ore reserves* in this discussion). This may be based on a classification of in situ block grade estimates after making some allowance for dilution and ore loss or on estimates of recovered fractions of the blocks that will be mined above a chosen cutoff grade and of the corresponding grades.
- 3) *Minability*, referring to that tonnage and grade that is estimated to be recoverable or achievable through mining on a local block by block basis, but which is also contained within economic ultimate pit limits and is demonstrably minable through the life of the project (*minable ore reserves* in this discussion).
- 4) *Metallurgical*, referring to that fraction of metal content in run-of-mine mill feed that will be recovered by the processing plant and will therefore report within the product

to be sold, e.g., the concentrate (*recoverable metal* in this discussion).

Discussion of each of these factors follows. While each is important in a thorough evaluation of recoverable ore reserves, all but the question of mining dilution are treated very briefly in this section because these aspects are addressed in greater detail elsewhere in this handbook. Mining dilution in different ore-body environments, however, is discussed at some length; first because its significance has often been underestimated historically, and second because geostatistics provides a means by which the effects of mining selectivity and ore dilution can be studied.

Cutoff Grade

To geostatistically estimate reserves for deposits that have gradational boundaries, a cutoff grade must be selected, above which material will be classified as ore and below which it will be considered as waste. Obviously, the ore reserve figures calculated will depend on the cutoff grade chosen.

Ore reserves, whether they be geologic or minable, are normally estimated and reported based on a so called *internal* cutoff grade. This is that grade at which the value of recoverable metal contained in each ton of ore just exceeds the cost of recovering that metal. Within defined pit limits, the near-cutoff grade material will typically be mined either as ore or waste in order to uncover higher grade material below. Therefore, this internal cutoff grade calculation generally only includes the cost difference between ore and waste mining and not the total mining cost. The internal cutoff grade does not include an allowance to carry the cost of any waste stripping that will inevitably be necessary to expose the ore. To be economic, the pit increments at the ultimate pit wall will therefore contain ore of higher grade than the internal cutoff grade.

In long-term mine planning, an analysis of cutoff grade should not be limited to a simple break-even calculation. For a given mill capacity, an increase in cutoff grade provides a means of increasing mill feed grade and concentrate production, and hence annual profitability. Coincident with such an increase in cutoff grade, however, will be an increase in the mining capacity required to satisfy the plant at full feed capacity and a decrease in the ore body's life.

Generally, a set of cutoff grades can be identified for each production period that simultaneously balances each production stage (i.e., mining, concentrating, refining) at its maximum capacity. A further set of "optimum" cutoff grades can also be determined that maximize the present value of future cash flows based on given assumptions regarding product price, costs, and capacities (Lane, 1964; Blackwell, 1970; Taylor, 1972).

To evaluate recoverable reserves, cutoff grades must therefore be chosen. Depending on the company's objectives these grades may or may not include some minimum profit element and may or may not represent an optimum choice. A rigorous analysis of the economic effects of varying cutoff grades throughout the life of the mine cannot be properly undertaken until an ultimate pit and a corresponding sequence of pit development phases has been determined. This permits an evaluation of tonnage-grade inventories for each logical and minable pit expansion or phase, that in turn provides the necessary input data for variable cutoff grade analysis. The estimate of recoverable ore reserves that is finally provided might be based on a variable cutoff grade strategy through time or a fixed break-even cutoff grade, depending on the management philosophy and the amount of detail with which the property is being evaluated.

In some mineral deposits cutoff grades are chosen such that maximum (or minimum) product grades or qualities are achieved. Examples can be found in iron ore, chromite, coal, limestone, bauxite, phosphate, etc. These deposits have a very high proportion of ore mineral (compared to copper, gold deposits, etc.) and generally high homogeneity and continuity. Mining therefore tends to require blending from various parts of the deposit to achieve a run-of-mine product that meets a set of required constituent grades, i.e., minimum calorific value, minimum iron, maximum ash, minimum silica, etc. The emphasis is on control of product quality and impurities rather than on marginal economic value.

Typically, a geostatistical ore-body model is obtained by dividing a deposit into blocks of a given size for which in situ grade estimates can be calculated by kriging. Blocks are then classified as ore or waste and accumulated, depending on the cutoff grade.

Where it is proposed that mining should or will be more selective in terms of ore/waste discrimination than the in situ model block size, geostatistics provides a means of estimating that portion of each block that will be recovered as ore along with its corresponding grade. Such estimates of so-called "recovered fractions" and "recovered grades" (by mining) are made, assuming a certain selective mining unit size and orientation and a certain cutoff grade. In this case recoverable ore reserves within a given zone are evaluated by accumulating estimates of recoverable fractions or volumes and recoverable grades for all blocks or cells within the volume of interest.

The resultant reserve estimate is valid for the selected cutoff grade only. Any classification of material above various grade limits in this reserve merely represents an estimate of the distribution of ore tonnages within grade intervals that could be expected if the deposit was mined with the chosen degree of mining selectivity and the chosen cutoff grade. To obtain reserves at some other cutoff grade, it is necessary to reestimate the corresponding recoverable fractions and grades block by block. Alternatively, adjustments may be made on a global basis.

Further discussion on the calculation of cutoff grades is given in Chapter 5, "Planning and Design of Surface Mines," while the geostatistical estimation of recoverable fractions and grades given a cutoff grade is addressed in the following.

Mining Recovery

Having generated a computerized geologic model for a mineral deposit, an ore reserve estimation team should make estimates of dilution in ore grade and loss of metal content to the waste dump. This assessment should recognize external dilution and losses that may occur at the ore zone boundary (i.e., inclusion of peripheral barren or low-grade material) or internally (i.e., inclusion of internal waste that may be incompletely discarded during mining) or perhaps unavoidably through the ore reserve modeling process.

The significance of these factors will depend on the ore body's geometry and distribution of mineralization, along with the degree of mining selectivity and production control that should be practiced or that can be achieved operationally. It will also depend on the methodology used in generating the in situ block grade model.

Dilution displaces higher grade ore from mill feed, reduces head grades, and hence directly reduces profitability. In addition, because process tailings often have a constant assay for a given mineral processing facility, dilution also tends to reduce metallurgical recovery irrespective of whether the waste minerals have deleterious chemical effects on the

process or not. Consequently it is important, particularly for low-grade and more erratic deposits. It is very rare that a mining operation realizes the mill-head grades that were predicted from exploration drilling and feasibility level ore reserve estimation. Ore tonnage is typically higher than expected and the grade lower—a situation that leads to lower than expected returns. This may necessitate a mill expansion early in the mine's life so as to meet the scheduled concentrate production levels that are necessary to service the mine's debt repayment schedule. In some cases, oversight of the significance of this factor has contributed to financial failure of the mining operation.

Often "apparent dilution" arises indirectly in response to the reserve estimation methodology adopted. For example, in a highly nonhomogeneous deposit, polygonal methods will tend to overestimate ore grade and underestimate ore tonnage partially because these methods fail to smooth the grade distribution of samples. They effectively assume that mining will differentiate ore from waste on the basis of volumes equivalent to the size of the samples. In other words, they fail to recognize the grade variance-volume relationship wherein the grades of the selective mining units are known to have a reduced variability compared with samples, and therefore when a cutoff grade is applied, mined tonnages and grades do not match those that were predicted.

Problems can occur when the grades of large in situ blocks are estimated via some sort of multi-sample smoothing procedure (be it geostatistical, inverse distance weighting, etc.). Although this process may reliably estimate the overall average grade of these in situ blocks, a reserve generated simply by classifying these blocks as ore or waste depending on their grade may overestimate mined ore tonnage and underestimate mined grade. This is likely to be true whenever detailed grade information will be obtained, e.g., from blasthole assaying that is not available when calculating in situ reserves. The problem will be more pronounced where the homogeneity in the mineralization is poor.

In summary, dilution and ore loss must be recognized in ore reserve estimation in not only the traditional sense of improper ore zone boundary selectivity but also inherently

within the estimation methodology itself (i.e., oversmoothing) and in the fact that one is in effect estimating the boundary between ore and waste based on sparse exploration drilling rather than the close spaced blasthole assays that will be available in production.

An examination of some specific deposit environments and their geometries in terms of dilution and modeling impacts follows. For simplicity, only two general deposit categories—regular stratiform and irregular deposits—are discussed.

Regular Stratiform Deposits: Under this heading, we have the flat-lying, stratabound, single and multi-seam type of deposits as can be found in coal, bauxite, tar sands, phosphates, oil shale, etc. Such deposits, because of their small dip angles, are normally mined so as to respect the hanging wall and footwall surfaces as far as possible. Mining conforms to these surfaces rather than to horizontal benches.

It is common in such cases to construct a computerized gridded model of the deposit by estimating the elevations of hanging wall and footwall surfaces for each grid cell as shown in Fig. 53. Geostatistically, it is often better to estimate the footwall surface and seam thickness directly since the latter variable typically demonstrates good continuity in variogram analysis. The hanging wall surface is then calculated indirectly.

In this type of deposit there is normally a very sharp contact between the valuable mineral and the waste overburden and interburden strata. These interfaces have good continuity and can be estimated with high precision. However, depending on their local irregularity and on the mining equipment used, some dilution and loss will generally occur. The mining method will normally call for cleaning off all waste material from the hanging wall and consequently in this process some of the coal (or ore mineral as the case may be) is unavoidably mined and lost as waste. As the coal is extracted, it is similarly difficult to clean precisely to the footwall with high production mining equipment and consequently some waste dilution will typically occur.

Computerized seam-type modeling systems normally allow for the user to specify two thickness values to be used

Fig. 53. Regular flat-lying stratiform deposit.

for hanging wall losses and footwall dilution. Losses and dilution are then computed by multiplying these thicknesses by the cell area in plan view and the number of cells in the area of interest. Reserves are reduced by the loss quantity and increased by the dilution quantity at its estimated quality or grade (i.e., that of footwall waste). The thicknesses selected by the user are very much a matter of judgment based on past experience with other similar deposits; on the degree of irregularity in the seam surfaces; on the mining equipment selected (e.g., scrapers, dozer/loader, etc.); and on whether there is a difference in material properties (e.g., color, radioactivity, etc.) between the valuable mineral and the adjoining waste. In modeling a tar sands deposit, for example, it may be better to respect lithological or strata boundaries (e.g., sandstone containing the bitumen vs. barren shales) so as to simplify production control procedures and hence to minimize boundary dilution, rather than to define vertical ore and waste limits based on grade alone.

In addition to the footwall dilution and hanging wall loss problems in estimating recoverable reserves in stratabound deposits, one also must deal with internal waste bands or partings. These may or may not be of sufficient thickness to selectively discard as waste and are typically of limited areal extent. The footwalls and hanging walls of such partings are not normally modeled as surfaces but are interpolated into cells as an average parting thickness or perhaps as a waste fraction. The computer system then reports internal waste parting volumes separate from the mineral by accumulating these fractions or thicknesses over all cells within the area of interest.

To arrive at recoverable reserves, the reserve estimation team must then decide on what percentage of the parting volume will probably be discarded during mining and what will be washed out in a preparation or processing plant (if any). Having done so, quality or grade estimates of the recoverable mineral can be derived.

Let us now examine a regular stratiform deposit that again has sharp boundaries between the massive ore body and waste but which no longer can be easily mined so as to follow these boundaries exactly because of its steeply dipping attitude. Such a deposit is depicted in simple form in Fig. 54a. If the ore body was relatively soft and dipping at less than about 20°, dozers could be used to clean off hanging wall waste material and therefore minimize dilution during loading operations. Dozer attachments such as a so-called slope board can also be used to clear off hanging wall waste for more steeply dipping environments. For this discussion, however, let us assume that such dozer work is either not justified or possible, and that the ore body is to be mined in regular horizontal benches by front-end loaders or hydraulic excavators. Material will be dispatched as ore or waste depending on blasthole grades.

Because of its relatively high grade, its sharp boundaries, and its very strong downdip continuity, it is decided to geologically model this deposit for in situ reserves purposes using an inclined grid as shown in Fig. 54a. This approach normally permits maximum alignment of the model to the actual deposit footwalls and hanging walls compared with a regular horizontal block model or a variable thickness seam type model. In addition, geostatistical interpolation of grades into a multi-level, variable thickness seam model is mathematically very complex, cumbersome, and generally not justified.

More reliable kriged estimates of grade are likely for the inclined cuboid blocks proposed because the mineralization often demonstrates more dominant downdip continuity as opposed to horizontal continuity. In such inclined grid

models, the estimation is normally undertaken with only mineralized drill-hole samples rather than with a statistical mixture of barren and mineralized samples that can lead to theoretical and practical difficulties. This mixture, of course, would be the case if a regular horizontal block model was created from the outset.

Having created an inclined gridded model by kriging and estimated geologic reserves, it is now necessary to convert this model into one suitable for mine planning purposes because the deposit is to be surface mined on horizontal benches. A reliable assessment of dilution and loss impacts is therefore necessary.

At least one ore body modeling system known to the authors provides an effective means of handling this problem from a mining standpoint via a so-called grid rotation procedure. The system firstly subdivides all cells (ore and waste) of the inclined input matrix into a regular array of points as shown in Fig. 54a. A grade and a volume is assigned to each point (the volume is important if several inclined and overlapping grids of different cell size are to be combined). The user then specifies a horizontal grid of cells whose size is equivalent to a selective mining unit. The system merely conducts a weighted averaging of the grades of all points that fall within each new horizontally oriented small cell. In this way, the grades of cells along the deposit boundaries are diluted with adjacent waste or low grade material. In some cases, ore will be lost because when it is combined with the waste, the selective mining unit or new cell in the model will not make the cutoff grade. The resultant model of small selective mining units can be used for mine planning and minable reserves evaluation. Reserves are obtained through an accumulation of cells having grades above a selected cutoff value. In practice selective mining units will, of course, not be mined either as complete ore or waste cuboids. The ore/waste boundary will be determined on the basis of blastholes and hence, will be irregular. This concept, however, does provide a suitable and more reliable means of estimating ore for planning purposes.

This technique provides a means of geometrically handling dilution and ore loss and should give reasonable results as long as there is a sharp boundary and definite grade difference between the ore and waste zones. If the ore mineral is, for example, distinctly different in color than the hanging wall waste, greater vertical selectivity could be achieved using bulldozer slope boards or hydraulic shovels. In this way, more waste could be removed prior to ore mining, thus reducing dilution effects.

At the feasibility planning stages of a new mining property, an estimate is made of recoverable reserves on the basis of relatively sparse drill-hole data. When it comes to mining the deposit, the ore/waste boundary will typically be determined from close-spaced blasthole assay results and hence more information will be available from which to segregate waste from ore. This is illustrated in Fig. 54b. If one has blasthole grades available, local or global adjustments can be made to the deposit model and reserve estimates generated from exploration holes only. This can be done by increasing the variance of estimated selective mining unit grades in recognition of the fact that such units will have higher variability in practice due to the availability of blasthole assays.

Irregular Deposits: Two categories of mineral deposits that can be generally considered to have irregular geometry will be addressed here in terms of geostatistically estimating recoverable ore. The first is a moderately disseminated, somewhat spotty (in mineralization) type of deposit with very gradational boundaries, while the second is more vein-dom-

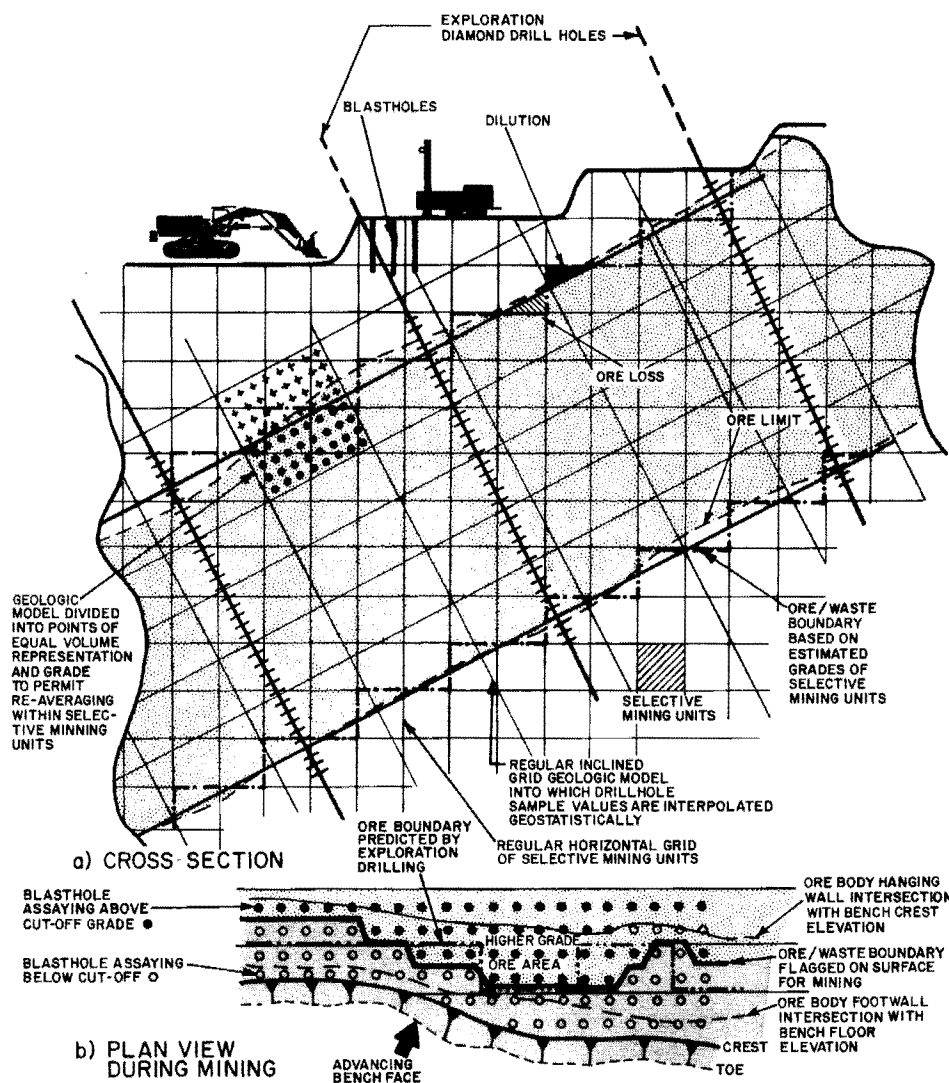

Fig. 54. Steeply dipping stratiform deposit.

inated and consists of intermixed barren and mineralized zones.

Consider the deposit in Fig. 55. A horizontal in situ block model was defined with lateral dimensions roughly one-third of the exploration drill-hole spacing. The frequency distribution of drill-hole samples was found to behave lognormally. Following a semivariogram analysis, the blocks were log-normally kriged resulting in the indicated grades. At this point, it would be possible to simply classify these in situ blocks as falling above or below the selected cutoff grade and report reserves accordingly. However, in this deposit it is recognized from an examination of drill core and from semivariogram studies that the mineralization has a high degree of short range variability (high nugget effect) even though the semivariogram range is relatively long and the sill variance relatively low.

It is further recognized that due to the nature of this deposit, potential exists for minimizing the mill size and hence the capital investment, and for maximizing mill head grades even though this may mean a higher cost operation involving a selective mining operation and engineered grade

control. It is proposed, therefore, to mine the deposit with greater ore to waste discernability or selectivity than the in situ block size. Recoverable reserve estimation must therefore attempt to take this into account.

As previously discussed, geostatistics recognizes that the value of a geologic variable is not only associated with its location but its support volume as well. Variability in grade for example decreases with increasing support size. If the impact of selective mining is to be estimated, then the first step is to develop a frequency distribution of selective mining unit grades within the in situ blocks. This process usually assumes that if the sample grades are distributed lognormally, then so will be the selective mining unit grades. To assume lognormality of small, mineralized selective mining units is often not unreasonable. However, this assumption becomes less reliable for larger units.

We have seen earlier ("Dispersion Variance and Grade Tonnage Curve") how, given semivariogram models for the deposit in question, one can determine the dispersion variance $\sigma_D^2(w \text{ in } W)$ of the small blocks w within the in situ blocks W . In fact, we do not know the true value of the in situ

blocks, but only their estimated value μ_k which was calculated by kriging, with an estimation variance σ_k^2 . What is needed is the variance of the small blocks with respect to their expected value μ_k . It is estimated as follows:

$$\sigma^2 = E[(\mu_w - \mu_k)^2] = \sigma_D^2(w \text{ in } W) + \sigma_k^2$$

If the sample values are lognormally distributed, the semi-variogram is either logarithmic or relative and the variance σ^2 is a relative variance. The corresponding logarithmic variance is calculated as follows:

$$\sigma_E^2 = \ln(1 + \sigma^2)$$

The assumption is then made that the selective mining units are either normally or lognormally distributed with a mean equal to the estimated block mean μ_k and variance σ^2 or σ_k^2 as calculated previously. The formulae given in "Dis-

persion Variance and Grade-Tonnage Curve" are used to estimate the fraction of the block that will be recovered as ore during mining, along with its average grade.

When applied to lognormally distributed values, this method of analysis is often referred to as the "lognormal shortcut." More complex methods can be used and have been successfully applied to selected deposits, such as the multivariate lognormal approach or disjunctive kriging. More detail on the theory and results achieved with these methods are given in Parker (1979), David (1977), and Journel and Huijbregts (1978).

An illustration of the method is shown in Fig. 55 where 90% of an in situ block is expected to be recoverable during mining at a grade of 1.92%. Recoverable fractions and grades are then accumulated over all blocks within the area of influence to arrive at a reserve estimate. Thus, in theory, we

are able to recognize the potential effects of selective mining using geostatistical methods.

This procedure is more accurate than one involving direct kriging of selective mining units themselves unless the drill-hole spacing is small enough to make such estimation meaningful. Typically, samples taken for ore body evaluation are taken far apart and justify estimation of in situ reserves for relatively large blocks only. Only when detailed grade information is available, usually through blasthole sampling, will it be possible and justified to estimate small selective mining units directly.

The procedure previously described does not locate within the block where the ore will be mined, but merely estimates that there will be a certain percentage of each block recovered above cutoff grade with the envisaged degree of mining selectivity. This apparent limitation is not really a problem for long term mine planning in that we are dealing with large volumes or combinations of such blocks for a given year's production estimate. What is more important is that we have recognized the potential effect of mining selectivity and attempted to estimate recoverable ore accordingly.

Let us now consider a deposit (Fig. 56) that comprises sharply bounded but extremely irregular ore lenses interspersed by barren rock. In this case, the sample grade distribution demonstrates a significant proportion of barren samples as well as a population of mineralized sample grades that can be regarded as being lognormally distributed. As one would expect, the frequency of barren subzones increases toward the deposit margins. It is again possible to use basically the same estimation approach as previously described but with some modification.

The normal procedure is to first composite the drill-hole grade data into regular lengths [say 2 m (6.6 ft)] and determine if the composites are mineralized (indicator 1) or barren (indicator 0). Variograms on the indicator are then evaluated and an estimate of the percentage of barren material is obtained by kriging for each in situ block from the surrounding drill holes. Next, the average grade of the portion mineralized is estimated based on neighboring mineralized samples only and the corresponding semivariogram. Problems may be encountered with this approach in poorly mineralized areas. The overall average grade of the in situ block is then obtained

Fig. 56. Irregular sharply bounded ore zone.

by combining barren and mineralized fractions. Block by block recovered fractions and grades are then computed as in the previous example, taking into account the mineralized portion only. Adjustment for the barren portion is required for tonnage estimation. Finally, reserves can be computed as before. This methodology has been used on numerous occasions particularly for high grade, nonhomogeneous ore bodies where a high degree of selectivity is necessary. A case study is given in Parker and Switzer (1975).

A key assumption in this procedure is that the entire barren proportion of each block can be discarded as waste during mining, irrespective of the degree of mining selectivity adopted. This is a reasonable assumption if the selective mining unit is very small and/or if the mineralized zones are separated by sufficient distances. Given this assumption, however, along with the inherent uncertainty in the estimation methodology itself, its susceptibility to error in estimating grades where recovered fractions are small (i.e., in the distribution tails), the fact that very limited data is available on such a small scale, and the inevitability of less than perfect selectivity in practice (production emphasis is normally on tonnage mined, not ore extracted), the ore reserve estimation team should make an additional subjective allow-

ance for dilution and metal loss. Such adjustments may represent a problem to some who regard geostatistics as the final and comprehensive tool, but realistically they are essential to the reliability and credibility of the recoverable reserves which are ultimately stated. This point underscores the importance of balanced judgment throughout the ore reserve estimation process to thoroughly review, question, and interpret the geostatistically derived data.

The concepts given in the previous example are perhaps more dramatically presented through the use of Fig. 57 that illustrates actual geostatistical estimates derived on a high grade base metal deposit. The figure shows a cross section of ore reserve blocks in this deposit for which individual estimates of recoverable fractions, recoverable grades, in situ block grades, and precision are given. From this figure, the following observations can be made:

1) That the uncertainty (lower left value) on average block grades is in general quite high and tends to increase toward the edges of the ore zone as one would expect (i.e., generally where the density of drill-hole data diminishes).

2) That the estimated percentage of recoverable ore (upper right value) increases toward the center of the ore zone reflecting greater ore concentration and continuity there.

b) SCHEMATICALLY

3) That in cases where the average or in-situ block grade is low, low proportions of very high grade ore are sometimes predicted for the ore recovered at the chosen selectivity. These estimates typically have poor reliability. The proportion recovered in these cases is low, however, and therefore the cumulative effect is not particularly significant.

4) That a picture of extreme variability is evident across the ore body. This variability supports the case for selective ore mining, at least as a basis for feasibility study planning.

5) Most of the metal content tends to be concentrated in the central core, or richest portion of the ore zone, that is some 18 to 36 m (60 to 120 ft) wide.

For illustrative purposes Fig. 57 also shows estimated grade distributions within a few distinctly different ore reserve blocks (insets on left). The frequency distributions of grade within these blocks show that barren material generally constitutes most of the waste. In other words, selective mining units, if they are mineralized, are probably going to be above cutoff grade. As previously described, the percentage barren in each case was estimated via an indicator kriging procedure that does *not* take into account the degree of mining selectivity intended. Taking mining selectivity into account is only possible in the procedure used to estimate recovered fractions of the mineralized portion using standard distribution theory.

Except in the case of a few very central blocks, this model suggests that most of the volume of a given ore reserve block will probably be discarded as waste. In fact, in this deposit only 28% of the total ore zone volume (ore reserve blocks whose in situ grade is greater than or equal to 0.01%) is estimated to be recoverable ore.

It is instructive to study the distribution of material within all of the ore-body blocks illustrated in Fig. 57. This distribution is shown schematically and numerically in Fig. 58. We find that for the envisioned $5 \times 5 \times 5$ -ft cube ($1.52 \times 1.52 \times 1.52$ -m) mining selectivity, 42% of this cross section's total in situ block volume would be mined as ore at a grade of 1.88%. If, however, the deposit was mined with no greater selectivity than the $75 \times 25 \times 10$ -ft ($22.87 \times 7.62 \times 3.05$ -m) in situ blocks, then we could expect significant dilution. With the same cutoff grade, 88% more tonnage would make ore grade. The average mined ore grade, however, would fall by almost one-half. The impact on mill size, capital costs, and process costs per kilogram (pound) of metal produced would obviously be dramatic. In such a high grade deposit, meticulous ore mining practices are warranted, at least for planning and costing purposes. In operation, such practices can always be easily relaxed but it can be embarrassing and costly to a mine faced with the need to implement the reverse.

A final but nevertheless very important subject under this heading of mining recovery is that of bulk density. Often mining companies obtain extensive specific gravities on core samples and use averages of these, perhaps by rock type, to convert their volumetric deposit model into a tonnage based reserve. Many ore deposits by their very nature are highly fractured and permeable. They therefore have a true in situ bulk density that is perhaps up to 10% less than the core sample specific gravity tests suggest. This directly affects the ore reserves and estimates of expected metal recovery. To gain a proper fix on this variable, it is wise to undertake true in situ bulk density determinations through the typical ex-

cavation and sand filling technique if ore exposures are available at outcrop or within underground bulk sampling drifts. Alternatively, such tests should be done on large diameter core samples rather than on small cores such that the volume occupied in fracture voids will be taken into account. Particular care must be taken in *vuggy* ores where normal specific gravity tests may be unreliable.

Minability

To provide an estimate of minable ore reserves, one must undertake a determination of potential ultimate or economic pit limits and accumulate estimates of block by block recovered fractions (or full blocks as the case may be) and grades within these limits. In addition, it should be demonstrated that the reserves contained within this ultimate pit are practically accessible and minable throughout the pit development sequence, by way of sufficient mine planning (Mathieson, 1982). Pit plans for the early production years should in particular be designed and evaluated in detail. Procedures for doing this are covered elsewhere in this book.

Metallurgical Recovery

As has been previously recognized in this section, the term recoverable reserves:

"assumes and should imply that the valuable constituent is economically recoverable and, second, in relation to the first few years of an operation, that recoverability is assured, since in these years there may not be time to cope with unexpected metallurgical problems. Acceptance of this future widens the reach of ore reserve estimation. Instead of being, as it so often is, a matter of dimensions and grade, it becomes an assessment of the whole production process from in situ definition to separation of a saleable product." (King, et al., 1982)

In relation to metallurgical recovery, ore grindability will affect mill throughput and hence the timing of cash flows. Sufficient testing should be undertaken on representative samples taken from all ore rock types, particularly if autogenous or semiautogenous milling is being contemplated. Such tests should also be made on composite samples representative of yearly mine production from different ore rock types.

It is becoming increasingly important to adequately address such "geo-metallurgical" factors within feasibility and early engineering studies. Significantly different metallurgical response and hence metal recoverability is often encountered between different lithologic units within the same ore body. This might be due to varying degrees of mineral dissemination and association between mineral assemblages (affecting the grind and process stages required for liberation); the degree of alteration, mineral tarnishing, etc., and hence the ore hardness and natural flotation potential; or perhaps an association with certain gangue minerals that may promote or inhibit concentration of the economic minerals of interest.

All of these factors strongly suggest that geologists and mining engineers must play an active part in collecting drill core and bulk samples for metallurgical testing to ensure that they are representative of each ore rock type to be mined. Particular care should be taken in blending these samples in a manner that properly models the proposed mine plan. It should be recognized in this sample selection stage that ore mined and delivered to the mill will normally constitute a mixture of other waste or ore rock types between or adjacent to those that primarily constitute the ore. Metallurgical tests on such dilution impacts may also be warranted.

In addition to the metallurgical team, geologists and mining engineers should also thoroughly review metallurgical

test data on the samples they have collected. Bench-scale tests on regular exploration core samples should be compared with tests done on larger diameter cores and/or bulk samples. Such reviews may suggest a need to recognize varying metallurgical response within the deposit modeling and reserve estimation methodology. This may simply entail the assignment of metallurgical parameters to each rock type or a more rigorous block-by-block estimation of these parameters.

In deposits that are highly variable metallurgically, it may be desirable to geostatistically evaluate the spatial correlation between metallurgical recovery and grindability with rock type and incorporate this into the recoverable reserve estimation procedures. Although not commonly done in the past, such studies, followed by kriging of metallurgical parameters, may prove in some highly variable deposits to be essential, if one is to gain sufficient confidence in the recoverability of metal from within a given mine plan, particularly in the early production years.

RESERVE REPORTING

To some, geostatistical ore reserve estimation is shrouded in mathematical complexity and technical jargon to such an extent, that they become skeptical of the resultant figures. They prefer to believe that the estimates have been generated in a "black box" sort of way, totally devoid of geologic and mining input. Because of this, and the general need to properly document any reserve estimate, some discussion on this subject is appropriate.

Unlike a conventional manual ore reserve estimate that is accompanied by largely self explanatory working maps, cross sections, and tables, the geostatistical reserve is based on a computer model and a much more involved calculation process. Adequate documentation of the methodology and the results is therefore essential if the reserve estimate is to have any credibility. The minable reserves estimation report should include as many of the following items as possible:

- 1) A complete discussion on the geologic setting of the ore body and the perceived geologic factors that influence and control the distribution of mineralization. Any conclusions that were reached, for example, with regard to relationships between mineral grades and structure and/or rock type, etc., should be addressed. Representative geologic maps and sections should be included. This should clearly establish to the reader that the "geo" in geostatistics has not been overlooked.

- 2) A brief exploration history for the deposit including details on any geophysics, drilling programs, core recovery, back reaming studies, bulk sampling, mapping, etc.

- 3) A complete description of the sample preparation and assaying procedures that were adopted. Results of all check assay analyses on split core, small and large diameter core, and between laboratories, etc., should be summarized along with any petrographic studies demonstrating distribution and gradation of mineral assemblages.

- 4) A discussion of results obtained from various specific gravity and in situ bulk density tests, justifying figures used within the reserve evaluation.

- 5) A description of the rock matrix or similar geologic input to the computer used to control geostatistical analysis and block interpolation.

- 6) Discussion on drill-hole coordinate survey reliability. A drill-hole location plan along with representative cross sections showing drill holes and grades should be provided.

- 7) Plots of actual semivariogram results within respective geologic zones of the deposit, and in different directions along

with semivariogram models chosen. This should include discussion on the geologic significance of the ore-body zonation that was used (i.e., mineralogic, alteration, rock type, structural, etc.) and any grade anisotropies found. The procedures and results of any cross validation or "jackknifing" tests conducted to verify the semivariogram models and the kriging method should also be given.

8) Grade frequency histograms of drill-hole bench composites within each grade zone, along with their cumulative probability plots and pertinent statistics.

9) A discussion of the modeling and kriging scheme used to estimate the reserves. Model dimensions, cell size, base-point coordinates and model orientation, etc., should be provided and illustrated. This should also permit the reader to understand the process used to estimate the various geologic zones in the deposit. The treatment of "fuzzy" boundaries, corresponding to gradational changes, and "sharp" boundaries, such as faults with major displacement, should be discussed here.

10) A series of bench plans and cross sections, showing not only the estimated block values and the precision with which they were estimated, but also the actual composite values used for estimation and the relevant geologic controls. These plans and sections should be reviewed in detail by the project geologists to assess the reasonableness of the results.

11) A summary of the block estimation errors or precisions by year for the first five to ten years of production and a discussion on how these errors might relate to a traditional ore reserve classification. This precision or uncertainty should incorporate not only the quantitatively derived estimation errors from kriging, but also a subjective estimate of the errors associated with grade zone definition, sample preparation, estimation methodology, and any known factors that, for whatever reason, could not be modeled, e.g., the effect of thin barren dikes cutting across an ore body that cannot be properly located.

12) A discussion on mining dilution, proposed mining methods, and inherent selectivity and procedures used within the ore reserve estimation process to account for these factors.

13) A plan of the proposed ultimate pit, along with the criteria used to derive it and plans demonstrating the minability of the ore reserves. It is important that the proposed mine plan and schedule incorporate sufficient insurance to cover a possible reduction in mined ore tonnage above the cutoff grade due to poor block estimates or perhaps greater mining selectivity due to blasthole data availability (i.e., discarding as waste some of the material predicted as ore). Obviously, if the mine plan does not recognize this possibility, however remote it is believed to be, there is a risk that the mine might either have to cut back on planned mill throughput or embark on a "crash" stripping program early in its life. The mine plan should provide sufficient preproduction waste stripping to obviate this concern.

14) A discussion on the chosen cutoff grade strategy and metallurgical characteristics related to geology insofar as they may effect annual process recoveries and metal production.

15) The reserve report should be accompanied by relevant geologic maps, data listings, bench plans, and cross sections.

In short, thorough documentation along the lines outlined increases a reviewer's "comfort index" by providing him with a full range of information from which he can understand the procedures used and the assumptions made. The reserve estimation team, through the discipline of preparing a detailed report, inevitably improves the reserve reliability and dramatically enhances the credibility of the result.

Statements on ore reserves in annual company reports should be well qualified such that they are truly meaningful to potential investors and shareholders. It should be remembered that the statement is only an estimate with uncertainty, and is far from being precise no matter how much statistical and geostatistical analysis is done. Statements should specify whether tonnage and grade estimates refer to in situ or recoverable reserves, should state the cutoff grade used, and what amount is considered to be in the measured (proven) and indicated (probable) categories. Comments should also be made regarding the level of risk in estimating reserves in the deposit in question in terms of its continuity and/or homogeneity.

Often, ore reserve estimation is treated as a mechanical process, of a purely mathematical nature, whose purpose is solely to manipulate a number of sample values to obtain tonnage and grade estimates. The result of this computational exercise is then summarized in statements of the form: "The ABC deposit contains 250,352,000 t (275.9 million st) of ore averaging 0.52%Cu." The numbers obtained are used by the mining company for internal financial and technical planning, and are published in stockholders reports, in a form that too often implies a high degree of certainty concerning their precision. Even though there is no question that reserve estimates must be made and disclosed, there is also a need for appropriate qualifications to be attached to these estimates, as to their meaning and the unavoidable imprecision involved.

Calculated reserves can represent global estimates characteristic of an entire deposit, independent of location, continuity, or exploitability. They can represent in-situ geologic reserves, where geologic controls and location are taken into account, but mining constraints have been ignored, except possibly in a very broad sense such as being subject to minimum thickness or grade constraints. If the necessary information is available, recoverable reserves could be calculated, taking into account mining method, mining selectivity, influence of cutoff grade, dilution, recovery possibly including metallurgical recovery, and other economic and technical constraints. Finally, minable reserves might be estimated as that ore tonnage and grade that is contained by and demonstrably minable within economic ultimate pit limits.

Clearly, the economic value of the ABC deposit will not be the same whether the 250,352,000 t (275.9 million st) of ore averaging 0.52% Cu represent global reserves, recoverable, or minable reserves. These reserve estimates will also have different meanings depending on the precision with which they are known. Estimation errors in excess of 50% are not uncommon, but in favorable conditions, the precision of the estimates may be as high as 10%. All of these factors must be taken into account when reporting reserve estimates internally and externally, as well as when using these estimates for decision purposes. We must remember that despite modern computer-based ore reserve estimation technologies, we are still typically dealing with relatively sparse data and often a highly variable ore body to be estimated. In consequence it is important that the estimating team appropriately convey their inherent uncertainty in the deposit model created or reserve estimate obtained.

3.4 Application of Methods

3.4.1 Precious Metal Deposits

DAVID S. BOLIN

INTRODUCTION

Precious metal deposits, for the purpose of the following discussion, are considered to be those in which gold and/or silver are the principal commodities, both in terms of metal content and value. Not included are those deposits in which either or both metals are recovered as a byproduct, even though such byproducts may constitute a significant percentage of the total dollar value of the ore, and, in some cases the deposit might not be economic to mine without the precious metal content. Also not included in this discussion are platinum group metal deposits, although this group of deposits is sometimes classed with the precious metals. This presentation is confined to lode deposits; placer deposits are discussed in a separate section of this volume.

The sampling and evaluation of precious metal deposits presents some unique and complex problems in ore reserve analysis. Many of these problems are related to the widely variable geological environments in which these deposits occur and the often highly erratic distribution of values within a deposit. The problems tend to be magnified due to the high unit value of the precious metals in which a relatively small error in the estimation of grade can produce a large variation in value.

Assaying of precious metal deposits has become an increasingly critical factor. This is particularly the case in recent years, with the decrease in economic cutoff grades in response to the dramatic increase in gold and silver prices. Average economic metal concentrations are now often in the range of only a fraction of a part per million, a level that requires great care in sample preparation and analytical procedures to produce reliable figures for reserve estimation.

While there have been many developments in geostatistical techniques and computer modeling for ore reserve computation, the fact remains that the most critical phase in the evaluation of a precious metal deposit is that of sampling. This is the phase most susceptible to the generation of errors and biases, and the numerical results of the sampling program provide the basic data for all subsequent calculations.

The design of a sampling program should be given careful consideration. The sampling program should be designed for each individual project and should take into account the geological environment and mineral distribution characteristics of the deposit. The sampling program must be executed with care and attention to detail if reliable results are to be obtained without excessive expenditures.

TYPES OF DEPOSITS

Gold and silver deposits occur in a wide range of geological environments and have a variety of physical and mineralogical characteristics. In the following discussions of deposit types, these various characteristics will be emphasized in as much as they impact on the design of a sampling program. The classification system utilized should not be considered to have any genetic connotations in the geological

sense. The details of the various deposit types are summarized on Table 1.

This table gives an indication of the average mineral distribution characteristics of the various types of deposits. The tonnage column gives the range of tonnages for deposits known or in production in 1982. The average ore grade given is the grade being produced in 1982; however, many of the mines have operated at higher grades in the past. The grade value given for gold deposits is gold grade, without respect to silver credits, and for silver deposits, the value given is silver grade without regard to gold credits. The range of ore values is the range of values expected to be encountered between the 5 and 95% limits of the frequency distribution of the deposit type.

The average grain size given is the expected range in particle size of the valuable mineral for each type of deposit. This is an estimated value, and in some deposits, the range can be considerably greater.

The last column, the expected coefficient of variability, gives an indication of the variability of ore grade, and therefore the degree of precision to which a given ore grade estimate can be carried out, even assuming the sampling and assaying to be perfectly executed. The coefficient of variability is defined as:

$$C = \frac{s}{w}$$

where C is the coefficient of variability, s is the sample standard deviation, and w is the sample mean. This coefficient is dependent upon sample size, and the value given here is for a sample weight of approximately 40 kg (88 lb), the amount in a 1.5 m (5.0 ft) exploration rotary drill intercept.

The higher the coefficient of variation, the more difficult will be the estimation of ore grades within narrow limits. In general, values of the coefficient between 1.0 and 1.5 will produce reasonably good precision on a grade estimate. Values between 1.5 and 2.5 will have only fair precision, and should be treated with caution. Values greater than 2.5 are likely to produce grade estimates with a very high degree of imprecision, a factor which must be considered in the final evaluation of a deposit.

Gold Deposits: Those deposits for which gold is the major constituent, both in content and value include the following:

- 1) Stratabound conglomerate deposits of the Witwatersrand type.
- 2) Hydrothermal veins and breccia zones of mesothermal and epithermal association.
- 3) Disseminated deposits, usually in volcanic or sedimentary rocks.

Stratabound Conglomerate Deposits: The Witwatersrand type gold deposits are the most prolific known in the free world. The type locality is the Witwatersrand basin of

Table 1. Sampling Characteristics of Precious Metal Deposits

Type of Deposit	Tonnage $t \times 10^6$	Average Ore Grade, g/t	Range of Ore Values, g/t	Average Grain Size, mm	Gold/ Silver Ratio	Coefficient of Variability
Gold/Silver						
Stratiform Conglomerate	0.5 - > 10	8 - 20	1 - 50	0.05 - 0.15	30	0.8 - 1.2
Veins and Breccias	0.1 - 5	10 - 40	1 - > 1000	0.1 - 10	5 - 15	+ 2.5
Disseminated Deposits						
Stratiform	0.5 - > 10	4 - 10	0.1 - 30	< .01	1 - 10	1.25 - 1.75
Disseminated-Hydrothermal	0.5 - > 100	1 - 6	0.1 - 30	< .01 - 0.10	1 - 5	1.5 - 2.5
Shear Zone	0.1 - > 10	1 - 10	0.1 - 50	0.05 - 0.1	1 - 5	2 - 4
Silver/Gold						
Veins and Breccias	0.1 - > 50	100 - 500	10 - > 1000	1 - 10	0.1 - 1	1.5 - > 3
Disseminated	0.5 - > 50	60 - 200	10 - > 1000	0.1 - 1	0.1 - 0.5	1.5 - 2.5

English equivalents: $1t \times 1.102\,311 = 1\text{ st}$; $1\text{ g/t} = 0.029\,03\text{ oz per st}$; $1\text{ mm} \times 0.03937 = 1\text{ in.}$

South Africa, although similar deposits are known in Canada, Brazil, and elsewhere. The deposits are characterized by usually thin conglomeratic beds of great lateral persistence. Mineralization and gold values tend to be rather uniform, sometimes, although not invariably, over distances of several hundred meters. The gold occurs as free gold with an average size of approximately $80\text{ }\mu\text{m}$. The gold/silver ratio averages about 30.

Due to the general regularity of the distribution of values, and the fine grain size at the gold, there is usually little difficulty in sampling deposits of this type. The upper and lower boundaries of the seams or "reefs" are usually quite sharp, although lateral boundaries can be poorly defined.

Hydrothermal Veins and Breccia Zones: Deposits of this type are responsible for the majority of the sampling problems associated with precious metal deposits. This category includes a wide variety of deposits including:

- 1) Gold-quartz veins such as those of the Canadian Shield and the Mother Lode region of California.
- 2) Gold-sulfide veins, with varying amounts of quartz, calcite or other gangue such as the Homestake deposit at Lead, SD, and Central City, CO.
- 3) Epithermal veins and breccia pipes such as those in the San Juan Mountains of Colorado and Goldfield, NV.

The gold in the first group usually occurs as the native element; however, in the other groups the gold may be free, bound in sulfide minerals, or, more rarely, as various gold tellurides. Vein boundaries are usually very sharp, and the gold mineralization tends to occur as discreet ore shoots within the veins. Values are normally very erratic, but grades may occasionally be in the range of $5\text{--}10\text{ kg/t}$ ($12\text{--}24\text{ lb per st}$). Grain size of the gold varies from 0.1 to over 10 mm (0.004 to 0.39 in.), a characteristic that further complicates sampling of deposits of this type.

Disseminated Deposits: Deposits in this category have received increasing attention with the steady increase in the price of gold in recent years and are the deposits usually mined by open pit methods. These deposits occur in a variety of geologic environments, but are most commonly encountered in volcanic and sedimentary rocks.

The deposits are characterized by relatively large tonnage with average grades that vary from 0.1 to about 6.0 g/t (0.003 to 0.175 oz per st). The ore bodies occur in stockworks and shear zones, as lenticular stratiform ore zones, and as columnar chimney-shaped bodies. These deposits, with a few exceptions, have not been extensively reported in the literature, but seem to fall into the following general types:

1) Stratiform deposits in carbonaceous sedimentary rocks, such as Carlin, NV.

2) Disseminated, often pipelike bodies in sedimentary or volcanic rocks such as Pueblo Viejo, Dominican Republic, or Round Mountain, NV.

3) Wide fracture or shear zones in various host rocks such as the Zortman-Landusky deposits of Montana.

Gold distribution in these deposits tends to be somewhat more regular than vein deposits. The boundaries of economic mineralization tend to be poorly defined and limits are often based on assay cutoffs. Within a single disseminated deposit, the range of values is usually somewhat more restricted than the vein deposits with values rarely exceeding 15 g/t (0.44 oz per st). In some deposits, economic mineralization is confined to the oxidized material due to metallurgical considerations.

Silver/Gold Deposits: Silver and silver/gold deposits occur primarily as veins and occasionally as disseminated deposits. Vein deposits, with the possible exception of the Cobalt, Ont., type, are most often epithermal deposits. Typical examples include Guanajuato, Mexico; Tonopah, NV; Comstock, NV; and the epithermal silver deposits of the Sierra Madre Occidental of Mexico. These deposits are most often encountered in volcanic terrains in the form of veins and breccia bodies. These deposits are usually of somewhat more complex mineralogy than gold veins and silver occurring as the native element, simple sulfides, silver sulfosalts, and tellurides. Base metal minerals are common, and most deposits contain at least minor gold values.

The vein deposits suffer the same problems as the vein gold deposits. The values vary from a few parts per million to several kilograms per ton, and distribution of values tends to be highly erratic. The vein walls are usually sharply defined, and economic values are often confined to discreet ore shoots with distinct tops and bottoms.

Known disseminated silver deposits are mostly stockwork or shear zone controlled, with the grade of mineralization closely related to degree of fracturing. The values tend to have a rather restricted range, usually varying between 60 to 300 g/t . Mineralization is more regular in distribution than the vein deposits, and the limits of economic values are usually defined by assay boundaries. Typical examples of this type include Delamar, ID; Rochester, NV; and, Calico, CA.

SAMPLING

The design of a sampling program for a precious metal project must be tailored to the type of mineralization known

or expected to be present, and to the amount of previous exploration or development of the property. Traditionally, precious metal deposits have been sampled by means of prospect pits, trenches, and underground development. Within more recent years, drilling, both core and noncore, has assumed a more prominent role in the evaluation of gold and silver deposits, particularly the disseminated types.

Channel Sampling

Channel sampling of underground or surface workings is the method most often applied to lenticular ore bodies of various types. In the classical application of the method, a channel of constant width and depth is cut across the vein or ore zone. If the vein is of less than mining width, the walls are usually sampled separately to provide information for the calculation of dilution.

In practice, the cutting of precise channel samples is a laborious and often very expensive process, and the collection of "chip channel" samples has become more common. If reasonable care is exercised in collecting the sample, the chip samples are often statistically indistinguishable from traditional channel samples.

Although usually applied to vein type deposits, channel or chip channel sampling of crosscuts and trenches is utilized in the evaluation of disseminated precious metal deposits. These samples are usually cut in a continuous line along the rib of a crosscut or trench with the length of individual samples varying from 1 to 3 m (3 to 10 ft). Veins or breccia zones are usually sampled separately.

Samples are cut with a hammer andmoil or, if available, an air or electric powered chisel. The cut sample is collected on a canvas tarp for homogenization and splitting if required. The mechanics of channel sampling have been described in numerous publications, for example, McKinstry (1948).

Drilling

Evaluation of precious metal deposits by drilling has become more common in recent years due to the increase in exploration for disseminated type deposits. Although drilling is applicable to vein, disseminated, and strataform deposits, the method has often proven to be of doubtful value in many vein occurrences. While drilling is often used to confirm the continuity of vein structure and mineralization, the assay values obtained are often unreliable. This is due to the usually highly variable distribution of values in vein systems and often poor sample recovery in fractured and brecciated veins.

Core Drilling: This drilling method provides lithological and structural information as well as providing a sample for assay; however it is usually the most expensive of the methods available for general use.

In instances where substantial drilling is required to evaluate a deposit, it is usually considered to be good practice to core a certain percentage of the holes in the drill program. The actual percentage will vary with the available budget and the degree of complexity of the geology, but usually averages about 10%.

Core samples offer the advantage that sample location can be closely defined, and there is little possibility of contamination or loss of values as long as recovery is good.

On the negative side, core drilling is expensive and the usual sample obtained (NX or BX) is relatively small. In cases where the ore boundaries are fairly well known, the cost can sometimes be lowered by rotary drilling to near the ore boundary and then continuing with core.

Noncore drilling: Noncore drilling techniques have become increasingly popular in recent years due to the low

cost relative to diamond drilling combined with the large number of holes required for the evaluation of high tonnage, low grade deposits. The noncore drilling methods in common use include: (1) conventional rotary drilling, (2) downhole hammer drilling, (3) reverse circulation drilling, and (4) percussion drilling. Each of these methods offers certain advantages and disadvantages. Percussion drilling, either from a small air-track machine or underground longhole drill, is usually very cheap and simple to operate. The disadvantages are the restricted depth range, usually less than 30 m (100 ft), the small diameter drill hole, and often poor sample recovery.

Conventional rotary or hammer drilling is relatively cheap, but there are often problems with sample recovery and possible contamination from uphole high grade zones. The equipment is usually truck-mounted and road construction may be required for access.

Some of the problems with sample recovery may be overcome by reverse circulation drilling. This technique utilizes double walled drill pipe with the circulating medium, air or water, passed down through the outer space and recovered, along with the sample, through the center pipe. The principal disadvantages are the relatively high cost and the size of the equipment.

The circulating medium for sample recovery may be either air, water, or mud, however, air is preferred if possible. Sample handling is considerably easier and the problems of obtaining water for drilling are avoided if air drilling is utilized.

A potential problem is the high pressure air required for reverse circulation drilling. It has sometimes been suspected that values may be lost by being blown into fractures, although this has not been documented. For this reason, some companies have gone to low pressure-high volume air systems in order to mitigate this possibility.

Sample recovery is usually by means of a cyclone attached to the air return system. These systems work quite well, and few problems have been reported. The recovery is calculated by weighing the sample recovered in each interval, commonly 2 or 3 m (6.5 to 10 ft). It is also a good practice to occasionally sample the cyclone dust overflow, particularly when oxidized silver mineralization is known or suspected to be present.

The drilling density determined for a given deposit is a function of the geologic complexity, continuity of mineralization and economic constraints. In disseminated deposits, spacing of drill holes is often 15 to 30 m (50 to 100 ft) in somewhat irregular mineralization, to as much as 100 m (330 ft) in more regular mineralization. The usual procedure is to begin the evaluation drilling at the widest spacing possible to outline the deposit, then fill in the drill pattern to a point that grade precision is considered to be adequately defined. Often variogram studies (see Section 4) may help in defining optimum drill spacing.

Bulk Sampling

At some point in the evaluation of a precious metal deposit, the collection of bulk samples for confirmation of grade estimates and metallurgical testing will be required. These samples are usually collected from existing underground workings, driving new headings or large diameter drilling.

In existing workings samples up to several tonnes may be obtained by slabbing along the rib of a crosscut or by cutting a channel down the back utilizing short drill holes and explosives. When driving new headings for sampling, samples may be taken on car lots.

SAMPLE PREPARATION

Sample Size

The size of the sample required to provide a reliable grade estimate is dependent upon the absolute content of the precious metals, the grain size of the valuable minerals, and various other factors. The general rule of thumb has always been "the bigger the better."

In practice, of course, sample size is limited by physical and economic constraints. Most samples taken for the evaluation of an ore deposit range from 10 to 50 kg (22 to 110 lb), the range of weight of a 1.5-m (5.0-ft) chip sample or drill interval. Once a sample has been broken, the determination of a representative sample weight becomes amenable to a more rigorous examination.

The problems of determining minimum sample weights have been investigated by many authors (for example, Gy, 1979; David, 1977, pp. 331-345). The work of Pierre Gy has resulted in the presentation of a formula for the calculation of the fundamental sample variance given various parameters of the ore in question. The simplified version of this formula is:

$$s^2(FE) = \frac{Cd^3}{Ms}$$

where $s^2(FE)$ is the fundamental sampling variance; d is the maximum particle diameter in centimeters; Ms is the sample weight in grams; and C is a sampling constant where $C = clfg$, c being the mineralogical composition factor, l the liberation factor, f the shape factor, and g the particle size distribution. This formula may be applied in several manners. The two most common are: (1) given a maximum acceptable sample variance, to calculate the sample weight necessary to achieve this precision; (2) given a sample size, to compute the expected precision of the estimate. This formula may be utilized for order-of-magnitude estimates of minimum sample size; however there are several factors that may produce substantial errors.

The mineralogical composition factor, c , is very simple to compute if the ore mineral is free gold in a siliceous matrix. In this case the factor is primarily a function of the gold assay grade. In complex silver ores in which silver may be present in several different minerals, the factor is not a simple function of grade and calculation should be made based on known or estimated mineral composition.

The liberation factor, l , may be difficult to estimate, particularly in gold deposits, due to the variation in size that may range from 30 μm (500 mesh) to 1680 μm (10 mesh) or larger in a single sample. It is always good practice to pan a crushed sample of the ore to obtain an idea of the size distribution of the gold particles.

The shape factor for most calculations is assumed at 0.5 that represents a spherical particle shape. Both gold and silver, particularly in the native form, often occur as wires, flakes, and other forms that may require an adjustment to the value of this factor.

While there are problems with the application of this formula to sampling of precious metal deposits, it has been used in several cases and has produced generally good results (Vallee, et al., 1976). The formula should not be applied blindly; the various components of the formula should be carefully evaluated in the light of the geological and mineralogical characteristics of the ore.

As an example, consider a 1.52-m (5.0-ft) intercept in

an 114 mm ($4\frac{1}{2}$ -in.) rotary drill hole. This sample will weigh approximately 40 kg (88 lb), and the maximum chip size should be about 6.4 mm (0.25 in.) and a gold particle size of 10 μm . What might be a minimum sample weight at this sample particle size to provide a 95% probability that a 5.0 g/t (0.15 oz per st) gold would be known within ± 1.0 g/t (0.03 oz per st)? Using a modified form of Gy's equations:

$$Ms = \frac{4cflgd^3A^2}{a^2}$$

where $c = 3.8 \times 10^6$, $f = 0.5$, $l = 0.001 - 0.65 = 0.04$, $g = 0.25$, $A = 5$, $a = 1$; $Ms = 494$ kg. This weight considerably exceeds the amount of sample available, which indicates that, under the stated parameters, the entire sample should be reduced prior to splitting in order to achieve a precision of 1.0 g/t (0.03 oz per st).

It is important to remember that application of this formula (or any other formula) will result in only an order-of-magnitude estimate for sample size. It is also significant that the theory applies only to broken material, that is that the sample weight is assumed to come from a mass of the same particle size, a condition that is not fulfilled in the direct sampling of ore in the ground. For further information and examples, refer to Gy (1979).

Sample Reduction

A series of comminution and sampling steps are required in order to arrive at a sample of one assay ton for analysis. Each of these steps involves potential errors and opportunity for the generation of biases. Each sampling step must be analyzed to ensure that sufficient sample weight of the proper size is being taken to produce reliable results. For example, a split half of a drill core weighing approximately 8 kg (17.6 lb) must be crushed prior to splitting. If the gold averages about 100 μm (150 mesh) in size and 5 g/t (0.15 oz per st) in grade, and the entire 8 kg (17.6 lb) is crushed to 1.0 mm (0.04 in.), and a 2-kg (4.4 lb) split is taken, then the sampling variance would be:

$$s^2(FE) = \frac{cflgd^3}{2000}$$

$$s^2(FE) = 0.076$$

where $c = 3.8 \times 10^6$, $f = 0.5$, $l = \sqrt{0.01 \div 0.1} = 0.32$, $g = 0.25$, and $d = 0.1$ cm (0.04 in.) that is a reasonable figure. On the other hand, if the core is crushed to only 6.4 mm (0.25 in.) prior to splitting, the calculated variance would be:
